Table of Contents

What is AWS Lambda?	1
How Lambda works	2
Key features	2
Related information	3
How it works	3
Lambda functions and function handlers	4
Lambda execution environment and runtimes	5
Events and triggers	5
Lambda permissions and roles	6
Running code	9
Creating event-driven architectures	25
Designing an application	38
Create your first function	46
Prerequisites	46
Create the function	48
Invoke the function	54
Clean up	57
Next steps	58
Example apps and patterns	60
File Processing	60
Database Integration	60
Scheduled Tasks	60
Long-running Workflows	61
Additional resources	61
File-processing app	61
Create the source code files	63
Deploy the app	66
Test the app	77
Next steps	84
Scheduled-maintenance app	85
Prerequisites	86
Downloading the example app files	87
Creating and populating the example DynamoDB table	97
Creating the scheduled-maintenance app	100

Testing the app	104
Next steps	105
Creating an Order Processing System with Lambda Durable Functions	105
Prerequisites	106
Create the Source Code Files	106
Deploy the App	107
Test the App	108
Next Steps	108
Development tools	110
Local development tools	110
Infrastructure as Code (IaC) tools	111
GitHub Actions tools	112
Powertools for AWS Lambda	112
Workflow and event management tools	112
Local development	113
Key benefits of local development	113
Prerequisites	113
Authentication and access control	114
Moving from console to local development	117
Working with functions locally	117
Convert your function to an AWS SAM template and use IaC tools	120
Next steps	120
GitHub Actions	121
Example workflow	121
Additional resources	122
Infrastructure as code (IaC)	122
IaC tools for Lambda	122
Using AWS SAM and Infrastructure Composer	124
Using AWS CDK	135
Powertools for AWS Lambda	146
Key benefits of Powertools for AWS	146
Integrating Powertools with AWS	146
Next steps	120
Workflows and events	147
Code-first orchestration with durable functions	147
Orchestrating workflows with Step Functions	148

Managing events with EventBridge and EventBridge Scheduler	149
Lambda durable functions	151
Key benefits	151
When to use durable functions	151
How durable functions compare to Step Functions	152
How it works	152
Next steps	154
Basic concepts	155
Durable execution	155
DurableContext	156
Steps	157
Wait States	157
Invoking other functions	158
Durable function configuration	159
See also	161
Creating durable functions	161
Prerequisites	162
Create the durable function	164
Invoke the durable function	170
Clean up	173
Next steps	173
Deploy with CLI	174
Using Infrastructure as Code	180
Durable functions or Step Functions	188
When to use durable functions	189
When to use Step Functions	189
Decision framework	189
Feature comparison	190
Hybrid architectures	191
Migration considerations	191
Related resources	191
Examples	191
Short-lived fault-tolerant processes	191
Long-running processes	196
Advanced patterns	204
Next steps	216

Security and permissions	216
Execution role permissions	216
State encryption	218
CloudTrail logging	218
Cross-account considerations	219
Inherited Lambda security features	219
Durable execution SDK	220
DurableContext	220
What the SDK does	221
How checkpointing works	221
Replay behavior	222
Available durable operations	223
How durable operations are metered	230
Supported runtimes	233
Invoking durable functions	236
Invocation methods	236
Qualified ARNs requirement	238
Understanding execution lifecycle	239
Invoking from application code	239
Chained invocations	241
Event source mappings	242
Retries	249
Idempotency	256
Testing durable functions	261
Local testing	261
Cloud testing	264
What to test	265
Testing strategy	266
Debugging failures	266
Monitoring durable functions	267
CloudWatch metrics	267
EventBridge events	269
AWS X-Ray tracing	271
Best practices	272
Write deterministic code	272
Design for idempotency	276

Manage state efficiently	278
Design effective steps	280
Use wait operations efficiently	280
Additional considerations	281
Additional resources	282
Lambda Managed Instances	283
Key capabilities	283
When to use Lambda Managed Instances	283
How it works	284
Concurrency model	284
Tenancy and isolation	284
Understanding managed instances	285
Pricing	285
How Lambda Managed Instances differs from the Lambda (default) compute type	285
Next steps	286
Getting started	287
Creating a Lambda Managed Instance function (console)	287
Creating a Lambda Managed Instance function (AWS CLI)	288
Core concepts	294
Capacity providers	295
Scaling	299
Security	302
Operator role	304
Execution environment	307
Version publishing	309
Runtimes	310
Supported runtimes	310
Runtime-specific considerations	310
Next steps	311
Java runtime	311
Node.js runtime	316
Python runtime	321
.NET runtime	323
Networking	327
Connectivity options	327
Public subnet with an internet gateway	328

VPC endpoints	329
Private subnet with NAT gateway	330
Choosing a connectivity option	330
Next steps	331
Monitoring	331
Available metrics	331
Metric frequency and retention	333
Viewing metrics in CloudWatch	333
Using metrics to optimize performance	333
Next steps	333
Quotas	334
Lambda API request quotas	334
Lambda Managed Instances resource quotas	334
Event source mapping quotas	335
Requesting a quota increase	335
Next steps	336
Best practices	336
Capacity provider configuration	336
Instance type selection	336
Function configuration	337
Scaling configuration	337
Security	338
Cost optimization	338
Monitoring and observability	338
Runtime-specific considerations	339
Next steps	339
Troubleshooting	340
Throttling and scaling issues	340
Concurrency issues	340
Performance issues	342
Capacity provider issues	343
Monitoring and observability issues	344
Getting additional help	346
Next steps	347
Lambda runtimes	348
Supported runtimes	348

New runtime releases	352
Runtime deprecation policy	353
Shared responsibility model	353
Runtime use after deprecation	355
Receiving runtime deprecation notifications	357
Deprecated runtimes	358
Runtime version updates	361
Backward compatibility	362
Runtime update modes	363
Two-phase runtime version rollout	364
Configuring runtime management	365
Runtime version roll-back	366
Runtime version updates	368
Shared responsibility model	370
Permissions	372
Get data about functions by runtime	373
Listing function versions that use a particular runtime	373
Identifying most commonly and most recently invoked functions	375
Runtime modifications	380
Language-specific environment variables	380
Wrapper scripts	380
Runtime API	384
Next invocation	385
Invocation response	386
Initialization error	386
Invocation error	388
OS-only runtimes	391
Building a custom runtime	392
Custom runtime tutorial	397
Open source repositories	405
Runtime Interface Clients	405
Event libraries	406
Container base images	407
Development tools	407
Sample projects	408
Configuring functions	409

.zip file archives	411
Creating the function	411
Using the console code editor	413
Updating function code	413
Changing the runtime	414
Changing the architecture	414
Using the Lambda API	415
Downloading your function code	415
CloudFormation	416
Encryption	416
Container images	423
Requirements	424
Using an AWS base image	425
Using an AWS OS-only base image	426
Using a non-AWS base image	427
Runtime interface clients	427
Amazon ECR permissions	428
Function lifecycle	431
Memory	432
When to increase memory	432
Using the console	433
Using the AWS CLI	433
Using AWS SAM	434
Accepting function memory recommendations (console)	434
Ephemeral storage	435
Use cases	435
Using the console	436
Using the AWS CLI	436
Using AWS SAM	436
Instruction sets (ARM/x86)	438
Advantages of using arm64 architecture	438
Requirements for migration to arm64 architecture	439
Function code compatibility with arm64 architecture	439
How to migrate to arm64 architecture	439
Configuring the instruction set architecture	440
Timeout	442

When to increase timeout	442
Using the console	442
Using the AWS CLI	443
Using AWS SAM	443
Configure durable functions	444
Enable durable execution	444
IAM permissions for durable functions	445
Configuration best practices	447
Environment variables	448
Create environment variables	448
Example scenario for environment variables	452
Retrieve environment variables	454
Defined runtime environment variables	455
Securing environment variables	457
Attaching functions to a VPC	461
Required IAM permissions	461
Attaching Lambda functions to an Amazon VPC in your AWS account	463
Internet access when attached to a VPC	466
IPv6 support	467
Best practices for using Lambda with Amazon VPCs	468
Understanding Hyperplane Elastic Network Interfaces (ENIs)	469
Using IAM condition keys for VPC settings	470
VPC tutorials	475
Attaching functions to resources in another account	476
Prerequisites	476
Create an Amazon VPC in your function's account	477
Grant VPC permissions to your function's execution role	477
Create a VPC peering connection request	478
Prepare your resource's account	479
Update VPC configuration in your function's account	480
Test your function	481
Internet access for VPC functions	483
Inbound networking	508
Considerations for Lambda interface endpoints	508
Creating an interface endpoint for Lambda	509
Creating an interface endpoint policy for Lambda	510

File system	512
Supported Regions	512
Execution role and user permissions	512
Configuring a file system and access point	513
Connecting to a file system (console)	514
Aliases	516
Using aliases	518
Weighted aliases	519
Versions	524
Creating function versions	525
Using versions	526
Granting permissions	527
Tags	528
Permissions required for working with tags	528
Using tags with the console	528
Using tags with the AWS CLI	530
Response streaming	532
Bandwidth limits for response streaming	533
VPC compatibility with response streaming	533
Writing functions	534
Invoking functions	536
Tutorial: Creating a response streaming function with a function URL	537
Invoking functions	543
Invoke a function synchronously	545
Asynchronous invocation	549
Error handling	550
Configuration	551
Retaining records	553
Invocation	563
Synchronous invocation limits	563
Asynchronous invocation for long-running workflows	563
Execution management APIs	564
Event source mappings	566
Event source mappings and triggers	566
Batching behavior	567
Provisioned mode	570

Event source mapping API	572
Event source mapping tags	572
Event filtering	577
Understanding event filtering basics	578
Handling records that don't meet filter criteria	580
Filter rule syntax	581
Attaching filter criteria to an event source mapping (console)	582
Attaching filter criteria to an event source mapping (AWS CLI)	583
Attaching filter criteria to an event source mapping (AWS SAM)	585
Encryption of filter criteria	585
Using filters with different AWS services	591
Testing in console	593
Invoking functions with test events	593
Creating private test events	594
Creating shareable test events	594
Deleting shareable test event schemas	596
Function states	597
Function states during updates	598
Retries	600
Recursive loop detection	602
Understanding recursive loop detection	602
Supported AWS services and SDKs	604
Recursive loop notifications	606
Responding to recursive loop detection notifications	607
Allowing a Lambda function to run in a recursive loop	608
Supported Regions for Lambda recursive loop detection	610
Function URLs	611
Creating a function URL (console)	612
Creating a function URL (AWS CLI)	614
Adding a function URL to a CloudFormation template	615
Cross-origin resource sharing (CORS)	616
Throttling function URLs	618
Deactivating function URLs	618
Deleting function URLs	618
Access control	619
Invoking function URLs	630

Monitoring function URLs	642
Function URLs vs Amazon API Gateway	643
Tutorial: Creating a webhook endpoint	649
Function scaling	663
Understanding and visualizing concurrency	663
Calculating concurrency for a function	668
Understanding reserved concurrency and provisioned concurrency	669
Reserved concurrency	670
Provisioned concurrency	672
How Lambda allocates provisioned concurrency	676
Comparing reserved concurrency and provisioned concurrency	677
Understanding concurrency and requests per second	678
Concurrency quotas	680
Configuring reserved concurrency	682
Configuring reserved concurrency	683
Accurately estimating required reserved concurrency for a function	685
Configuring provisioned concurrency	686
Configuring provisioned concurrency	687
Accurately estimating required provisioned concurrency for a function	689
Optimizing function code when using provisioned concurrency	690
Using environment variables to view and control provisioned concurrency behavior	691
Understanding logging and billing behavior with provisioned concurrency	691
Using Application Auto Scaling to automate provisioned concurrency management	692
Scaling behavior	697
Concurrency scaling rate	697
Monitoring concurrency	699
General concurrency metrics	699
Provisioned concurrency metrics	699
Working with the <code>ClaimedAccountConcurrency</code> metric	702
Building with Node.js	705
Runtime-included SDK versions	707
Using keep-alive	707
CA certificate loading	707
Experimental Node.js features	708
Handler	710
Set up your project	710

Example function	711
CommonJS and ES Modules	713
Node.js initialization	714
Handler naming conventions	715
Input event object	715
Valid handler patterns	716
Using the SDK for JavaScript	718
Accessing environment variables	719
Using global state	719
Best practices	719
Deploy .zip file archives	722
Runtime dependencies in Node.js	722
Creating a .zip deployment package with no dependencies	723
Creating a .zip deployment package with dependencies	723
Creating a Node.js layer for your dependencies	724
Dependency search path and runtime-included libraries	725
Creating and updating Node.js Lambda functions using .zip files	726
Deploy container images	733
AWS base images for Node.js	734
Using an AWS base image	735
Using a non-AWS base image	741
Layers	751
Package your layer content	751
Create the layer in Lambda	756
Add the layer to your function	757
Sample app	758
Context	759
Logging	761
Creating a function that returns logs	761
Using Lambda advanced logging controls with Node.js	763
Viewing logs in the Lambda console	769
Viewing logs in the CloudWatch console	769
Viewing logs using the AWS Command Line Interface (AWS CLI)	770
Deleting logs	773
Tracing	774
Using ADOT to instrument your Node.js functions	775

Using the X-Ray SDK to instrument your Node.js functions	775
Activating tracing with the Lambda console	776
Activating tracing with the Lambda API	777
Activating tracing with CloudFormation	777
Interpreting an X-Ray trace	778
Storing runtime dependencies in a layer (X-Ray SDK)	781
Building with TypeScript	782
Development environment	783
Type definitions for Lambda	784
Handler	786
Set up your project	786
Example function	787
CommonJS and ES Modules	789
Node.js initialization	790
Handler naming conventions	790
Input event object	791
Valid handler patterns	791
Using the SDK for JavaScript	794
Accessing environment variables	795
Using global state	795
Best practices	796
Deploy .zip file archives	798
Using AWS SAM	798
Using the AWS CDK	800
Using the AWS CLI and esbuild	803
Deploy container images	806
Using a Node.js base image to build and package TypeScript function code	806
Context	814
Logging	817
Tools and libraries	817
Using Powertools for AWS Lambda (TypeScript) and AWS SAM for structured logging	818
Using Powertools for AWS Lambda (TypeScript) and the AWS CDK for structured logging	820
Viewing logs in the Lambda console	824
Viewing logs in the CloudWatch console	824
Tracing	826

Using Powertools for AWS Lambda (TypeScript) and AWS SAM for tracing	827
Using Powertools for AWS Lambda (TypeScript) and the AWS CDK for tracing	829
Interpreting an X-Ray trace	833
Building with Python	834
Runtime-included SDK versions	835
Disabled Python features	836
Response format	836
Graceful shutdown for extensions	837
Handler	838
Example Python Lambda function code	838
Handler naming conventions	840
Using the Lambda event object	841
Accessing and using the Lambda context object	842
Valid handler signatures for Python handlers	842
Returning a value	843
Using the AWS SDK for Python (Boto3) in your handler	844
Accessing environment variables	845
Code best practices for Python Lambda functions	845
Deploy .zip file archives	848
Runtime dependencies in Python	848
Creating a .zip deployment package with no dependencies	849
Creating a .zip deployment package with dependencies	849
Dependency search path and runtime-included libraries	852
Using __pycache__ folders	854
Creating .zip deployment packages with native libraries	854
Creating and updating Python Lambda functions using .zip files	855
Deploy container images	863
AWS base images for Python	864
Using an AWS base image	865
Using a non-AWS base image	872
Layers	882
Package your layer content	882
Create the layer in Lambda	756
Add the layer to your function	888
Sample app	889
Context	890

Logging	892
Printing to the log	892
Using a logging library	893
Using Lambda advanced logging controls with Python	895
Viewing logs in Lambda console	899
Viewing logs in CloudWatch console	900
Viewing logs with AWS CLI	900
Deleting logs	903
Tools and libraries	903
Using Powertools for AWS Lambda (Python) and AWS SAM for structured logging	904
Using Powertools for AWS Lambda (Python) and AWS CDK for structured logging	908
Testing	915
Testing your serverless applications	916
Tracing	918
Using Powertools for AWS Lambda (Python) and AWS SAM for tracing	919
Using Powertools for AWS Lambda (Python) and the AWS CDK for tracing	921
Using ADOT to instrument your Python functions	926
Using the X-Ray SDK to instrument your Python functions	927
Activating tracing with the Lambda console	928
Activating tracing with the Lambda API	928
Activating tracing with CloudFormation	928
Interpreting an X-Ray trace	929
Storing runtime dependencies in a layer (X-Ray SDK)	932
Building with Ruby	934
Runtime-included SDK versions	935
Enabling Yet Another Ruby JIT (YJIT)	936
Handler	937
Ruby handler basics	937
Code best practices for Ruby Lambda functions	938
Deploy .zip file archives	941
Dependencies in Ruby	941
Creating a .zip deployment package with no dependencies	942
Creating a .zip deployment package with dependencies	942
Creating a Ruby layer for your dependencies	944
Creating .zip deployment packages with native libraries	944
Creating and updating Ruby Lambda functions using .zip files	946

Deploy container images	953
AWS base images for Ruby	954
Using an AWS base image	954
Using a non-AWS base image	961
Layers	971
Package your layer content	971
Create the layer in Lambda	756
Using gems from layers in a function	978
Add the layer to your function	979
Sample app	980
Context	981
Logging	982
Creating a function that returns logs	982
Viewing logs in the Lambda console	983
Viewing logs in the CloudWatch console	984
Viewing logs using the AWS Command Line Interface (AWS CLI)	984
Deleting logs	987
Working with the Ruby logger library	987
Tracing	989
Enabling active tracing with the Lambda API	994
Enabling active tracing with CloudFormation	995
Storing runtime dependencies in a layer	995
Building with Java	997
Handler	1001
Setting up your Java handler project	1001
Example Java Lambda function code	1002
Valid class definitions for Java handlers	1007
Handler naming conventions	1008
Defining and accessing the input event object	1009
Accessing and using the Lambda context object	1010
Using the AWS SDK for Java v2 in your handler	1011
Accessing environment variables	1012
Using global state	1013
Code best practices for Java Lambda functions	1013
Deploy .zip file archives	1016
Prerequisites	1016

Tools and libraries	1017
Building a deployment package with Gradle	1018
Using layers for dependencies	1019
Building a deployment package with Maven	1019
Uploading a deployment package with the Lambda console	1021
Uploading a deployment package with the AWS CLI	1023
Uploading a deployment package with AWS SAM	1024
Deploy container images	1027
AWS base images for Java	1028
Using an AWS base image	1029
Using a non-AWS base image	1038
Layers	1050
Package your layer content	1050
Create the layer in Lambda	756
Add the layer to your function	1053
Custom serialization	1055
When to use custom serialization	1055
Implementing custom serialization	1056
Testing custom serialization	1057
Custom startup behavior	1058
Understanding the JAVA_TOOL_OPTIONS environment variable	1058
Log4j patch for Log4Shell	1060
Ahead-of-Time (AOT) and CDS caches	1061
Context	1062
Context in sample applications	1064
Logging	1066
Creating a function that returns logs	1066
Using Lambda advanced logging controls with Java	1068
Implementing advanced logging with Log4j2 and SLF4J	1071
Tools and libraries	1074
Using Powertools for AWS Lambda (Java) and AWS SAM for structured logging	1075
Viewing logs in the Lambda console	1079
Viewing logs in the CloudWatch console	1079
Viewing logs using the AWS Command Line Interface (AWS CLI)	1080
Deleting logs	1083
Sample logging code	1083

Tracing	1085
Using Powertools for AWS Lambda (Java) and AWS SAM for tracing	1086
Using Powertools for AWS Lambda (Java) and the AWS CDK for tracing	1088
Using ADOT to instrument your Java functions	1100
Using the X-Ray SDK to instrument your Java functions	1100
Activating tracing with the Lambda console	1101
Activating tracing with the Lambda API	1101
Activating tracing with CloudFormation	1102
Interpreting an X-Ray trace	1102
Storing runtime dependencies in a layer (X-Ray SDK)	1105
X-Ray tracing in sample applications (X-Ray SDK)	1106
Sample apps	1108
Building with Go	1110
Go runtime support	1110
Tools and libraries	1111
Handler	1112
Setting up your Go handler project	1112
Example Go Lambda function code	1113
Handler naming conventions	1116
Defining and accessing the input event object	1116
Accessing and using the Lambda context object	1117
Valid handler signatures for Go handlers	1118
Using the AWS SDK for Go v2 in your handler	1119
Accessing environment variables	1120
Using global state	1120
Code best practices for Go Lambda functions	1121
Context	1123
Supported variables, methods, and properties in the context object	1123
Accessing invoke context information	1124
Using the context in AWS SDK client initializations and calls	1126
Deploy .zip file archives	1127
Creating a .zip file on macOS and Linux	1127
Creating a .zip file on Windows	1129
Creating and updating Go Lambda functions using .zip files	1132
Deploy container images	1139
AWS base images for deploying Go functions	1139

Go runtime interface client	1140
Using an AWS OS-only base image	1140
Using a non-AWS base image	1147
Layers	1156
Logging	1157
Creating a function that returns logs	1157
Viewing logs in the Lambda console	1159
Viewing logs in the CloudWatch console	1159
Viewing logs using the AWS Command Line Interface (AWS CLI)	1159
Deleting logs	1163
Tracing	1164
Using ADOT to instrument your Go functions	1165
Using the X-Ray SDK to instrument your Go functions	1165
Activating tracing with the Lambda console	1165
Activating tracing with the Lambda API	1166
Activating tracing with CloudFormation	1166
Interpreting an X-Ray trace	1167
Building with C#	1170
Development environment	1170
Installing the .NET project templates	1170
Installing and updating the CLI tools	1171
Handler	1172
Setting up your C# handler project	1172
Example C# Lambda function code	1173
Class library handlers	1177
Executable assembly handlers	1178
Valid handler signatures for C# functions	1179
Handler naming conventions	1179
Serialization in C# Lambda functions	1180
File-based functions	1183
Accessing and using the Lambda context object	1183
Using the SDK for .NET v3 in your handler	1184
Accessing environment variables	1185
Using global state	1185
Simplify function code with the Lambda Annotations framework	1186
Code best practices for C# Lambda functions	1187

Deployment package	1189
NET Lambda Global CLI	1190
AWS SAM	1196
AWS CDK	1199
ASP.NET	1203
Layers	1208
Deploy container images	1209
AWS base images for .NET	1210
Using an AWS base image	1210
Using a non-AWS base image	1212
Native AOT compilation	1217
Lambda runtime	1217
Prerequisites	1218
Getting started	1218
Serialization	1221
Trimming	1222
Troubleshooting	1223
Context	1224
Logging	1226
Creating a function that returns logs	1226
Using Lambda advanced logging controls with .NET	1227
Tools and libraries	1234
Using Powertools for AWS Lambda (.NET) and AWS SAM for structured logging	1235
Viewing logs in the Lambda console	1238
Viewing logs in the CloudWatch console	1238
Viewing logs using the AWS Command Line Interface (AWS CLI)	1238
Deleting logs	1242
Tracing	1243

What is AWS Lambda?

Tip

Join Serverless experts for free hands-on workshops to learn how to build Serverless applications with best practices. [Click here](#) to sign up.

AWS Lambda is a compute service that runs code without the need to manage servers. Your code runs, scaling up and down automatically, with pay-per-use pricing. To get started, see [Create your first function](#).

You can use Lambda for:

- **File processing:** Process files automatically when uploaded to Amazon Simple Storage Service. See [file processing examples](#) for details.
- **Long-running workflows:** Use [durable Lambda functions](#) to build stateful, multi-step workflows that can run for up to one year. Perfect for order processing, approval workflows, human-in-the-loop processes, and complex data pipelines that need to remember their progress.
- **Database operations and integration examples:** Respond to database changes and automate data workflows. See [database examples](#) for details.
- **Scheduled and periodic tasks:** Run automated operations on a regular schedule using EventBridge. See [scheduled task examples](#) for details.
- **Stream processing:** Process real-time data streams for analytics and monitoring. See [Kinesis Data Streams](#) for details.
- **Web applications:** Build scalable web apps that automatically adjust to demand.
- **Mobile backends:** Create secure API backends for mobile and web applications.
- **IoT backends:** Handle web, mobile, IoT, and third-party API requests. See [IoT](#) for details.

For pricing information, see [AWS Lambda Pricing](#).

How Lambda works

When using Lambda, you are responsible only for your code. Lambda runs your code on a high-availability compute infrastructure and manages all the computing resources, including server and operating system maintenance, capacity provisioning, automatic scaling, and logging.

Because Lambda is a serverless, event-driven compute service, it uses a different programming paradigm than traditional web applications. The following model illustrates how Lambda works:

1. You write and organize your code in [Lambda functions](#), which are the basic building blocks you use to create a Lambda application.
2. You control security and access through [Lambda permissions](#), using [execution roles](#) to manage what AWS services your functions can interact with and what resource policies can interact with your code.
3. Event sources and AWS services [trigger](#) your Lambda functions, passing event data in JSON format, which your functions process (this includes event source mappings).
4. [Lambda runs your code](#) with language-specific runtimes (like Node.js and Python) in execution environments that package your runtime, layers, and extensions.

Tip

To learn how to build **serverless solutions**, check out the [Serverless Developer Guide](#).

Key features

Configure, control, and deploy secure applications:

- [Environment variables](#) modify application behavior without new code deployments.
- [Versions](#) safely test new features while maintaining stable production environments.
- [Lambda layers](#) optimize code reuse and maintenance by sharing common components across multiple functions.
- [Code signing](#) enforce security compliance by ensuring only approved code reaches production systems.

Scale and perform reliably:

- [Concurrency and scaling controls](#) precisely manage application responsiveness and resource utilization during traffic spikes.
- [Lambda SnapStart](#) significantly reduce cold start times. Lambda SnapStart can provide as low as sub-second startup performance, typically with no changes to your function code.
- [Response streaming](#) optimize function performance by delivering large payloads incrementally for real-time processing.
- [Container images](#) package functions with complex dependencies using container workflows.

Connect and integrate seamlessly:

- [VPC networks](#) secure sensitive resources and internal services.
- [File system](#) integration that shares persistent data and manage stateful operations across function invocations.
- [Function URLs](#) create public-facing APIs and endpoints without additional services.
- [Lambda extensions](#) augment functions with monitoring, security, and operational tools.

Related information

- To start using Lambda, see [Create your first Lambda function](#).
- For a list of example applications, see [Getting started with example applications and patterns](#).

How Lambda works

Lambda functions are the basic building blocks you use to build Lambda applications. To write functions, it's essential to understand the core concepts and components that make up the Lambda programming model. This section will guide you through the fundamental elements you need to know to start building serverless applications with Lambda.

- [Lambda functions and function handlers](#) - A Lambda function is a small block of code that runs in response to events. Functions can be standard (up to 15 minutes) or [durable](#) (up to one year). Functions are the basic building blocks you use to build applications. Function handlers are the entry point for event objects that your Lambda function code processes.

- [Lambda execution environment and runtimes](#) - Lambda execution environments manage the resources required to run your function. For [durable functions](#), the execution environment includes automatic state management and checkpointing capabilities. Runtimes are the language-specific environments your functions run in.
- [Events and triggers](#) - Other AWS services can invoke your functions in response to specific events. For durable functions, events can also trigger resumption of paused workflows.
- [Lambda permissions and roles](#) - Control who can access your functions and what other AWS services your functions can interact with. durable functions require additional permissions for state management and extended execution.

Tip

If you want to start by understanding serverless development more generally, see [Understanding the difference between traditional and serverless development](#) in the *AWS Serverless Developer Guide*.

Lambda functions and function handlers

In Lambda, **functions** are the fundamental building blocks you use to create applications. A Lambda function is a piece of code that runs in response to events, such as a user clicking a button on a website or a file being uploaded to an Amazon Simple Storage Service (Amazon S3) bucket. With durable functions, your code can pause execution between steps, maintaining state automatically, making them ideal for long-running workflows like order processing or content moderation. You can think of a function as a kind of self-contained program with the following properties.

A Lambda **function handler** is the method in your function code that processes events. When a function runs in response to an event, Lambda runs the function handler. Data about the event that caused the function to run is passed directly to the handler. While the code in a Lambda function can contain more than one method or function, Lambda functions can only have one handler.

To create a Lambda function, you bundle your function code and its dependencies in a deployment package. Lambda supports two types of deployment package, [.zip file archives](#) and [container images](#).

- A function has one specific job or purpose
- They run only when needed in response to specific events
- They automatically stop running when finished

Lambda execution environment and runtimes

Lambda functions run inside a secure, isolated [execution environment](#) which Lambda manages for you. For [durable functions](#), the execution environment includes additional components for state management and workflow coordination. The execution environment manages the processes and resources that are needed to run your function. When a function is first invoked, Lambda creates a new execution environment for the function to run in. After the function has finished running, Lambda doesn't stop the execution environment right away; if the function is invoked again, Lambda can re-use the existing execution environment.

The Lambda execution environment also contains a *runtime*, a language-specific environment that relays event information and responses between Lambda and your function. Lambda provides a number of [managed runtimes](#) for the most popular programming languages, or you can create your own.

For managed runtimes, Lambda automatically applies security updates and patches to functions using the runtime.

Events and triggers

You can also invoke a Lambda function directly by using the Lambda console, [AWS CLI](#), or one of the [AWS Software Development Kits \(SDKs\)](#). It's more usual in a production application for your function to be invoked by another AWS service in response to a particular event. For example, you might want a function to run whenever an item is added to an Amazon DynamoDB table.

To make your function respond to events, you set up a **trigger**. A trigger connects your function to an event source, and your function can have multiple triggers. When an event occurs, Lambda receives event data as a JSON document and converts it into an object that your code can process. You might define the following JSON format for your event and the Lambda runtime converts this JSON to an object before passing it to your function's handler.

Example custom Lambda event

```
{
```

```
"Location": "SEA",
"WeatherData":{
  "TemperaturesF":{
    "MinTempF": 22,
    "MaxTempF": 78
  },
  "PressuresHPa":{
    "MinPressureHPa": 1015,
    "MaxPressureHPa": 1027
  }
}
```

Stream and queue services like Amazon Kinesis or Amazon SQS, Lambda use an [event source mapping](#) instead of a standard trigger. Event source mappings poll the source for new data, batch records together, and then invoke your function with the batched events. For more information, see [How event source mappings differ from direct triggers](#).

To understand how a trigger works, start by completing the [Use an Amazon S3 trigger](#) tutorial, or for a general overview of using triggers and instructions on creating a trigger using the Lambda console, see [Integrating other services](#).

Lambda permissions and roles

For Lambda, there are two main types of [permissions](#) that you need to configure:

- Permissions that your function needs to access other AWS services
- Permissions that other users and AWS services need to access your function

The following sections describe both of these permission types and discuss best practices for applying least-privilege permissions.

Permissions for functions to access other AWS resources

Lambda functions often need to access other AWS resources and perform actions on them. For example, a function might read items from a DynamoDB table, store an object in an S3 bucket, or write to an Amazon SQS queue. To give functions the permissions they need to perform these actions, you use an [execution role](#).

A Lambda execution role is a special kind of AWS Identity and Access Management (IAM) [role](#), an identity you create in your account that has specific permissions associated with it defined in a *policy*.

Every Lambda function must have an execution role, and a single role can be used by more than one function. When a function is invoked, Lambda assumes the function's execution role and is granted permission to take the actions defined in the role's policy.

When you create a function in the Lambda console, Lambda automatically creates an execution role for your function. The role's policy gives your function basic permissions to write log outputs to Amazon CloudWatch Logs. To give your function permission to perform actions on other AWS resources, you need to edit the role to add the extra permissions. The easiest way to add permissions is to use an AWS [managed policy](#). Managed policies are created and administered by AWS and provide permissions for many common use cases. For example, if your function performs CRUD operations on a DynamoDB table, you can add the [AmazonDynamoDBFullAccess](#) policy to your role.

Permissions for other users and resources to access your function

To grant other AWS service permission to access your Lambda function, you use a [resource-based policy](#). In IAM, resource-based policies are attached to a resource (in this case, your Lambda function) and define who can access the resource and what actions they are allowed to take.

For another AWS service to invoke your function through a trigger, your function's resource-based policy must grant that service permission to use the `lambda:InvokeFunction` action. If you create the trigger using the console, Lambda automatically adds this permission for you.

To grant permission to other AWS users to access your function, you can define this in your function's resource-based policy in exactly the same way as for another AWS service or resource. You can also use an [identity-based policy](#) that's associated with the user.

Best practices for Lambda permissions

When you set permissions using IAM policies, [security best practice](#) is to grant only the permissions required to perform a task. This is known as the principle of *least privilege*. To get started granting permissions for your function, you might choose to use an AWS managed policy. Managed policies can be the quickest and easiest way to grant permissions to perform a task, but they might also include other permissions you don't need. As you move from early development through test and production, we recommend you reduce permissions to only those needed by defining your own [customer-managed policies](#).

The same principle applies when granting permissions to access your function using a resource-based policy. For example, if you want to give permission to Amazon S3 to invoke your function, best practice is to limit access to individual buckets, or buckets in particular AWS accounts, rather than giving blanket permissions to the S3 service.

Running code with Lambda

When you write a Lambda function, you are creating code that will run in a unique serverless environment. Understanding how Lambda actually runs your code involves two key aspects: the programming model that defines how your code interacts with Lambda, and the execution environment lifecycle that determines how Lambda manages your code's runtime environment.

The Lambda programming model

Programming model functions as a common set of rules for how Lambda works with your code, regardless of whether you're writing in Python, Java, or any other supported language. The programming model includes your runtime and handler.

For standard functions:

1. Lambda receives an event.
2. Lambda uses the runtime to prepare the event in a format your code can use.
3. The runtime sends the formatted event to your handler.
4. Your handler processes the event using the code you've written.

For Durable Functions:

1. Lambda receives an event
2. The runtime prepares both the event and `DurableContext`
3. Your handler can:
 - Process steps with automatic checkpointing
 - Pause execution without consuming resources
 - Resume from the last successful checkpoint
 - Maintain state between steps

Essential to this model is the *handler*, where Lambda sends events to be processed by your code. Think of it as the entry point to your code. When Lambda receives an event, it passes this event and some context information to your handler. The handler then runs your code to process these events - for example, it might read a file when it's uploaded to Amazon S3, analyze an image, or update a database. Once your code finishes processing an event, the handler is ready to process the next one.

The Lambda execution model

While the programming model defines how Lambda interacts with your code, Execution environment is where Lambda actually runs your function — it's a secure, isolated compute space created specifically for your function.

Each environment follows a lifecycle that varies between standard and durable functions:

Standard Functions (up to 15 minutes):

1. **Initialization:** Environment setup and code loading
2. **Invocation:** Single execution of function code
3. **Shutdown:** Environment cleanup

Durable Functions (up to 1 year):

1. **Initialization:** Environment and durable state setup
2. **Invocation:** Multiple steps with automatic checkpointing
3. **Wait States:** Pause execution without resource consumption
4. **Resume:** Restart from last checkpoint
5. **Shutdown:** Cleanup of durable state

This environment handles important aspects of running your function. It provides your function with memory and a /tmp directory for temporary storage. **For Durable Functions, it also manages:**

- Automatic state persistence between steps
- Checkpoint storage and recovery
- Wait state coordination
- Progress tracking across long-running executions

Understanding the Lambda programming model

Lambda offers two programming models: standard functions that run up to 15 minutes, and Durable Functions that can run up to one year. While both share core concepts, Durable Functions add capabilities for long-running, stateful workflows.

Lambda provides a programming model that is common to all of the runtimes. The programming model defines the interface between your code and the Lambda system. You tell Lambda the entry point to your function by defining a *handler* in the function configuration. The runtime passes in objects to the handler that contain the invocation *event* and the *context*, such as the function name and request ID.

For Durable Functions, the handler also receives a `DurableContext` object that provides:

- Checkpointing capabilities through `step()`
- Wait state management through `wait()` and `waitForCallback()`
- Automatic state persistence between invocations

When the handler finishes processing the first event, the runtime sends it another. For Durable Functions, the handler can pause execution between steps, and Lambda will automatically save and restore state when the function resumes. The function's class stays in memory, so clients and variables that are declared outside of the handler method in *initialization code* can be reused. To save processing time on subsequent events, create reusable resources like AWS SDK clients during initialization. Once initialized, each instance of your function can process thousands of requests.

Your function also has access to local storage in the `/tmp` directory, a transient cache that can be used for multiple invocations. For more information, see [Execution environment](#).

When [AWS X-Ray tracing](#) is enabled, the runtime records separate subsegments for initialization and execution.

The runtime captures logging output from your function and sends it to Amazon CloudWatch Logs. In addition to logging your function's output, the runtime also logs entries when function invocation starts and ends. This includes a report log with the request ID, billed duration, initialization duration, and other details. If your function throws an error, the runtime returns that error to the invoker.

Note

Logging is subject to [CloudWatch Logs quotas](#). Log data can be lost due to throttling or, in some cases, when an instance of your function is stopped.

Key differences for Durable Functions:

- State is automatically persisted between steps
- Functions can pause execution without consuming resources
- Steps are automatically retried on failure
- Progress is tracked through checkpoints

Lambda scales your function by running additional instances of it as demand increases, and by stopping instances as demand decreases. This model leads to variations in application architecture, such as:

- Unless noted otherwise, incoming requests might be processed out of order or concurrently.
- Do not rely on instances of your function being long lived, instead store your application's state elsewhere.
- Use local storage and class-level objects to increase performance, but keep to a minimum the size of your deployment package and the amount of data that you transfer onto the execution environment.

For a hands-on introduction to the programming model in your preferred programming language, see the following chapters.

- [Building Lambda functions with Node.js](#)
- [Building Lambda functions with Python](#)
- [Building Lambda functions with Ruby](#)
- [Building Lambda functions with Java](#)
- [Building Lambda functions with Go](#)
- [Building Lambda functions with C#](#)
- [Building Lambda functions with PowerShell](#)

Understanding the Lambda execution environment lifecycle

Lambda execution environments support both standard functions (up to 15 minutes) and Durable Functions (up to one year). While both share the same basic lifecycle, Durable Functions add state management capabilities for long-running workflows.

Lambda invokes your function in an execution environment, which provides a secure and isolated runtime environment. The execution environment manages the resources required to run your

function. The execution environment also provides lifecycle support for the function's runtime and any [external extensions](#) associated with your function.

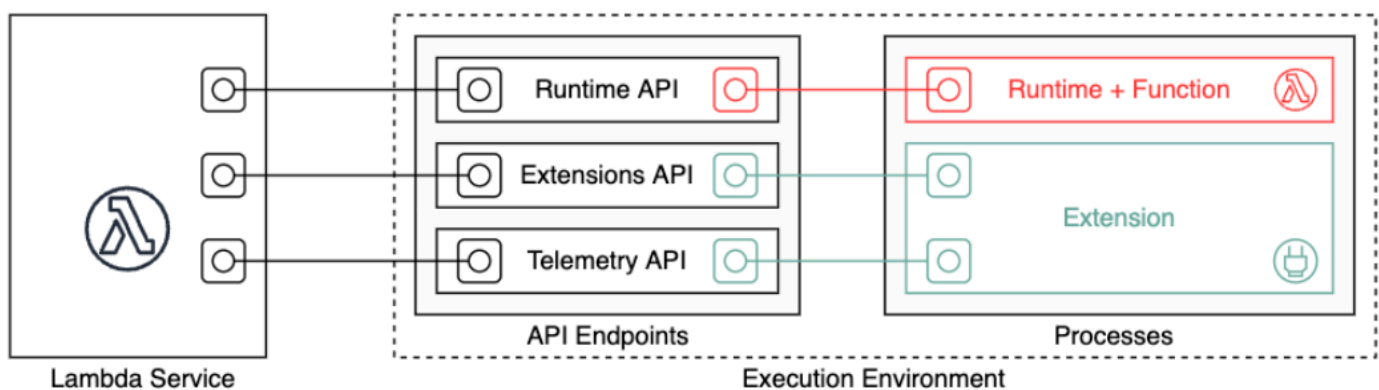

For Durable Functions, the execution environment includes additional components for:

- State persistence between steps
- Checkpointing management
- Wait state coordination
- Progress tracking

📘 Lambda Managed Instances execution environment

If you are using [Lambda Managed Instances](#), the execution environment has important differences compared to Lambda (default) functions. Managed Instances support concurrent invocations, use a different lifecycle model, and run on customer-owned infrastructure. For detailed information about the Managed Instances execution environment, see [Understanding the Lambda Managed Instances execution environment](#).

The function's runtime communicates with Lambda using the [Runtime API](#). Extensions communicate with Lambda using the [Extensions API](#). Extensions can also receive log messages and other telemetry from the function by using the [Telemetry API](#).

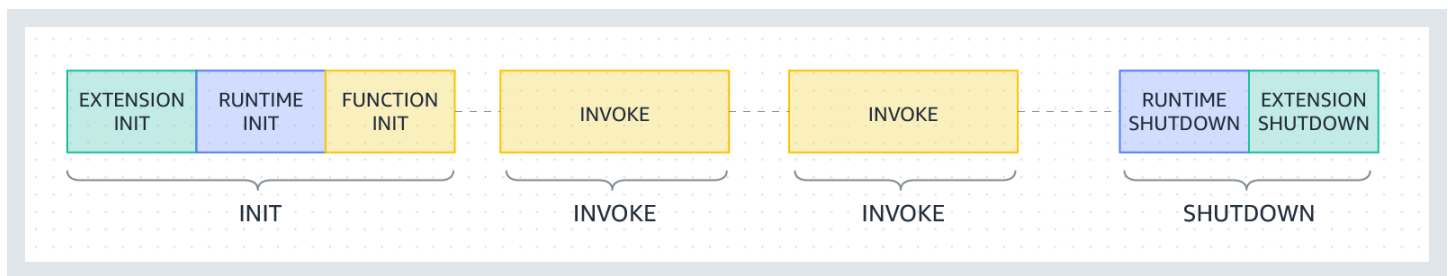

When you create your Lambda function, you specify configuration information, such as the amount of memory available and the maximum execution time allowed for your function. Lambda uses this information to set up the execution environment.

The function's runtime and each external extension are processes that run within the execution environment. Permissions, resources, credentials, and environment variables are shared between the function and the extensions.

Topics

- [Lambda execution environment lifecycle](#)
- [Cold starts and latency](#)
- [Reducing cold starts with Provisioned Concurrency](#)
- [Optimizing static initialization](#)

Lambda execution environment lifecycle

Each phase starts with an event that Lambda sends to the runtime and to all registered extensions. The runtime and each extension indicate completion by sending a Next API request. Lambda freezes the execution environment when the runtime and each extension have completed and there are no pending events.

The lifecycle phases for Durable Functions include:

- **Init:** Standard initialization plus durable state setup
- **Invoke:** Can include multiple step executions with automatic checkpointing
- **Wait:** Function can pause execution without consuming resources
- **Resume:** Function restarts from last checkpoint
- **Shutdown:** Cleanup of durable state and resources

Topics

- [Init phase](#)
- [Failures during the Init phase](#)
- [Restore phase \(Lambda SnapStart only\)](#)

- [Invoke phase](#)
- [Failures during the invoke phase](#)
- [Shutdown phase](#)

Init phase

In the Init phase, Lambda performs three tasks:

- Start all extensions (`Extension init`)
- Bootstrap the runtime (`Runtime init`)
- Run the function's static code (`Function init`)
- Run any before-checkpoint [runtime hooks](#) (Lambda SnapStart only)

The Init phase ends when the runtime and all extensions signal that they are ready by sending a Next API request. The Init phase is limited to 10 seconds. If all three tasks do not complete within 10 seconds, Lambda retries the Init phase at the time of the first function invocation with the configured function timeout.

When [Lambda SnapStart](#) is activated, the Init phase happens when you publish a function version. Lambda saves a snapshot of the memory and disk state of the initialized execution environment, persists the encrypted snapshot, and caches it for low-latency access. If you have a before-checkpoint [runtime hook](#), then the code runs at the end of Init phase.

Note

The 10-second timeout doesn't apply to functions that are using provisioned concurrency, SnapStart, or Lambda Managed Instances. For provisioned concurrency, SnapStart, and Managed Instances functions, your initialization code can run for up to 15 minutes. The time limit is 130 seconds or the configured function timeout (maximum 900 seconds), whichever is higher.

When you use [provisioned concurrency](#), Lambda initializes the execution environment when you configure the PC settings for a function. Lambda also ensures that initialized execution environments are always available in advance of invocations. You may see gaps between your function's invocation and initialization phases. Depending on your function's runtime and memory

configuration, you may also see variable latency on the first invocation on an initialized execution environment.

For functions using on-demand concurrency, Lambda may occasionally initialize execution environments ahead of invocation requests. When this happens, you may also observe a time gap between your function's initialization and invocation phases. We recommend you to not take a dependency on this behavior.

Failures during the Init phase

If a function crashes or times out during the Init phase, Lambda emits error information in the INIT_REPORT log.

Example — INIT_REPORT log for timeout

```
INIT_REPORT Init Duration: 1236.04 ms Phase: init Status: timeout
```

Example — INIT_REPORT log for extension failure

```
INIT_REPORT Init Duration: 1236.04 ms Phase: init Status: error Error Type:  
Extension.Crash
```

If the Init phase is successful, Lambda doesn't emit the INIT_REPORT log unless [SnapStart](#) or [provisioned concurrency](#) is enabled. SnapStart and provisioned concurrency functions always emit INIT_REPORT. For more information, see [Monitoring for Lambda SnapStart](#).

Restore phase (Lambda SnapStart only)

When you first invoke a [SnapStart](#) function and as the function scales up, Lambda resumes new execution environments from the persisted snapshot instead of initializing the function from scratch. If you have an after-restore [runtime hook](#), the code runs at the end of the Restore phase. You are charged for the duration of after-restore runtime hooks. The runtime must load and after-restore runtime hooks must complete within the timeout limit (10 seconds). Otherwise, you'll get a SnapStartTimeoutException. When the Restore phase completes, Lambda invokes the function handler (the [Invoke phase](#)).

Failures during the Restore phase

If the Restore phase fails, Lambda emits error information in the RESTORE_REPORT log.

Example — RESTORE_REPORT log for timeout

```
RESTORE_REPORT Restore Duration: 1236.04 ms Status: timeout
```

Example — RESTORE_REPORT log for runtime hook failure

```
RESTORE_REPORT Restore Duration: 1236.04 ms Status: error Error Type: Runtime.ExitError
```

For more information about the RESTORE_REPORT log, see [Monitoring for Lambda SnapStart](#).

Invoke phase

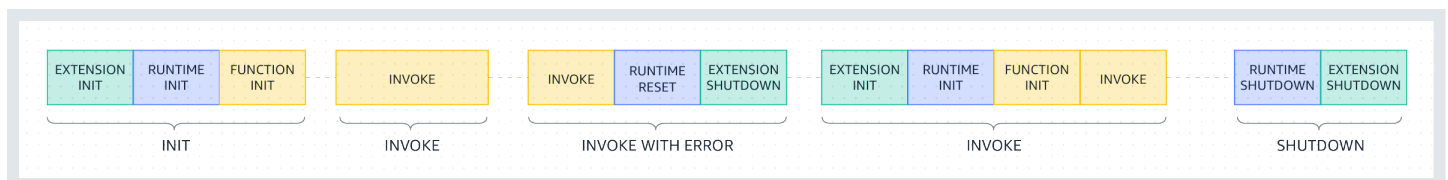

When a Lambda function is invoked in response to a Next API request, Lambda sends an Invoke event to the runtime and to each extension.

The function's timeout setting limits the duration of the entire Invoke phase. For example, if you set the function timeout as 360 seconds, the function and all extensions need to complete within 360 seconds. Note that there is no independent post-invoke phase. The duration is the sum of all invocation time (runtime + extensions) and is not calculated until the function and all extensions have finished executing.

The invoke phase ends after the runtime and all extensions signal that they are done by sending a Next API request.

Failures during the invoke phase

If the Lambda function crashes or times out during the Invoke phase, Lambda resets the execution environment. The following diagram illustrates Lambda execution environment behavior when there's an invoke failure:

In the previous diagram:

- The first phase is the **INIT** phase, which runs without errors.
- The second phase is the **INVOKE** phase, which runs without errors.
- At some point, suppose your function runs into an invoke failure (common causes include function timeouts, runtime errors, memory exhaustion, VPC connectivity issues, permission

errors, concurrency limits, and various configuration problems). For a complete list of possible invocation failures, see [the section called “Invocation”](#). The third phase, labeled **INVOKE WITH ERROR**, illustrates this scenario. When this happens, the Lambda service performs a reset. The reset behaves like a Shutdown event. First, Lambda shuts down the runtime, then sends a Shutdown event to each registered external extension. The event includes the reason for the shutdown. If this environment is used for a new invocation, Lambda re-initializes the extension and runtime together with the next invocation.

Note that the Lambda reset does not clear the `/tmp` directory content prior to the next init phase. This behavior is consistent with the regular shutdown phase.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

If your function's system log configuration is set to plain text, this change affects the log messages captured in CloudWatch Logs when your function experiences an invoke failure. The following examples show log outputs in both old and new formats.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

Example CloudWatch Logs log output (runtime or extension crash) - old style

```
START RequestId: c3252230-c73d-49f6-8844-968c01d1e2e1 Version: $LATEST
RequestId: c3252230-c73d-49f6-8844-968c01d1e2e1 Error: Runtime exited without
providing a reason
Runtime.ExitError
END RequestId: c3252230-c73d-49f6-8844-968c01d1e2e1
REPORT RequestId: c3252230-c73d-49f6-8844-968c01d1e2e1 Duration: 933.59 ms Billed
Duration: 934 ms Memory Size: 128 MB Max Memory Used: 9 MB
```

Example CloudWatch Logs log output (function timeout) - old style

```
START RequestId: b70435cc-261c-4438-b9b6-efe4c8f04b21 Version: $LATEST
```

```
2024-03-04T17:22:38.033Z b70435cc-261c-4438-b9b6-efe4c8f04b21 Task timed out after
3.00 seconds
END RequestId: b70435cc-261c-4438-b9b6-efe4c8f04b21
REPORT RequestId: b70435cc-261c-4438-b9b6-efe4c8f04b21 Duration: 3004.92 ms Billed
Duration: 3117 ms Memory Size: 128 MB Max Memory Used: 33 MB Init Duration: 111.23
ms
```

The new format for CloudWatch logs includes an additional status field in the REPORT line. In the case of a runtime or extension crash, the REPORT line also includes a field `ErrorType`.

Example CloudWatch Logs log output (runtime or extension crash) - new style

```
START RequestId: 5b866fb1-7154-4af6-8078-6ef6ca4c2ddd Version: $LATEST
END RequestId: 5b866fb1-7154-4af6-8078-6ef6ca4c2ddd
REPORT RequestId: 5b866fb1-7154-4af6-8078-6ef6ca4c2ddd Duration: 133.61 ms Billed
Duration: 214 ms Memory Size: 128 MB Max Memory Used: 31 MB Init Duration: 80.00
ms Status: error Error Type: Runtime.ExitError
```

Example CloudWatch Logs log output (function timeout) - new style

```
START RequestId: 527cb862-4f5e-49a9-9ae4-a7edc90f0fda Version: $LATEST
END RequestId: 527cb862-4f5e-49a9-9ae4-a7edc90f0fda
REPORT RequestId: 527cb862-4f5e-49a9-9ae4-a7edc90f0fda Duration: 3016.78 ms Billed
Duration: 3101 ms Memory Size: 128 MB Max Memory Used: 31 MB Init Duration: 84.00
ms Status: timeout
```

- The fourth phase represents the **INVOKE** phase immediately following an invoke failure. Here, Lambda initializes the environment again by re-running the **INIT** phase. This is called a *suppressed init*. When suppressed inits occur, Lambda doesn't explicitly report an additional **INIT** phase in CloudWatch Logs. Instead, you may notice that the duration in the REPORT line includes an additional **INIT** duration + the **INVOKE** duration. For example, suppose you see the following logs in CloudWatch:

```
2022-12-20T01:00:00.000-08:00 START RequestId: XXX Version: $LATEST
2022-12-20T01:00:02.500-08:00 END RequestId: XXX
2022-12-20T01:00:02.500-08:00 REPORT RequestId: XXX Duration: 3022.91 ms
Billed Duration: 3000 ms Memory Size: 512 MB Max Memory Used: 157 MB
```

In this example, the difference between the REPORT and START timestamps is 2.5 seconds. This doesn't match the reported duration of 3022.91 milliseconds, because it doesn't take into account the extra **INIT** (suppressed init) that Lambda performed. In this example, you can infer that the actual **INVOKE** phase took 2.5 seconds.

For more insight into this behavior, you can use the [Accessing real-time telemetry data for extensions using the Telemetry API](#). The Telemetry API emits INIT_START, INIT_RUNTIME_DONE, and INIT_REPORT events with phase=invoke whenever suppressed inits occur in between invoke phases.

- The fifth phase represents the **SHUTDOWN** phase, which runs without errors.

Shutdown phase

When Lambda is about to shut down the runtime, it sends a Shutdown event to each registered external extension. Extensions can use this time for final cleanup tasks. The Shutdown event is a response to a Next API request.

Duration limit: The maximum duration of the Shutdown phase depends on the configuration of registered extensions:

- 0 ms – A function with no registered extensions
- 500 ms – A function with a registered internal extension
- 2,000 ms – A function with one or more registered external extensions

If the runtime or an extension does not respond to the Shutdown event within the limit, Lambda ends the process using a SIGKILL signal.

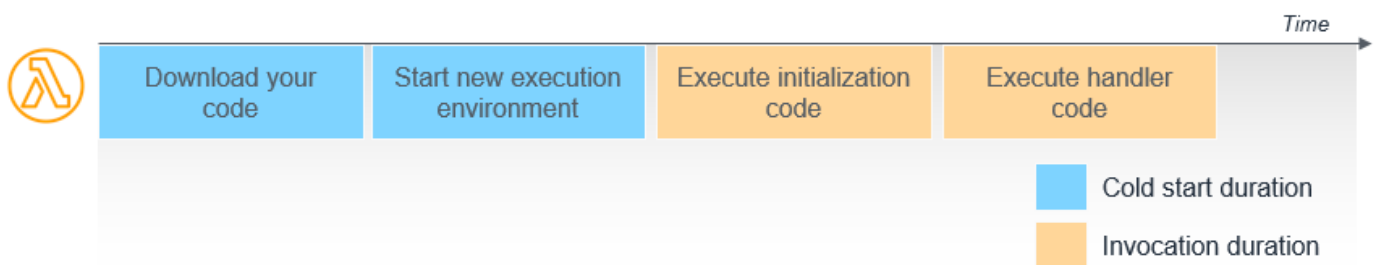

After the function and all extensions have completed, Lambda maintains the execution environment for some time in anticipation of another function invocation. However, Lambda terminates execution environments every few hours to allow for runtime updates and maintenance—even for functions that are invoked continuously. You should not assume that the execution environment will persist indefinitely. For more information, see [Implement statelessness in functions](#).

When the function is invoked again, Lambda thaws the environment for reuse. Reusing the execution environment has the following implications:

- Objects declared outside of the function's handler method remain initialized, providing additional optimization when the function is invoked again. For example, if your Lambda function establishes a database connection, instead of reestablishing the connection, the original connection is used in subsequent invocations. We recommend adding logic in your code to check if a connection exists before creating a new one.
- Each execution environment provides between 512 MB and 10,240 MB, in 1-MB increments, of disk space in the `/tmp` directory. The directory content remains when the execution environment is frozen, providing a transient cache that can be used for multiple invocations. You can add extra code to check if the cache has the data that you stored. For more information on deployment size limits, see [Lambda quotas](#).
- Background processes or callbacks that were initiated by your Lambda function and did not complete when the function ended resume if Lambda reuses the execution environment. Make sure that any background processes or callbacks in your code are complete before the code exits.

Cold starts and latency

When Lambda receives a request to run a function via the Lambda API, the service first prepares an execution environment. During this initialization phase, the service downloads your code, starts the environment, and runs any initialization code outside of the main handler. Finally, Lambda runs the handler code.

In this diagram, the first two steps of downloading the code and setting up the environment are frequently referred to as a “cold start”. You are [charged for this time](#), and it adds latency to your overall invocation duration.

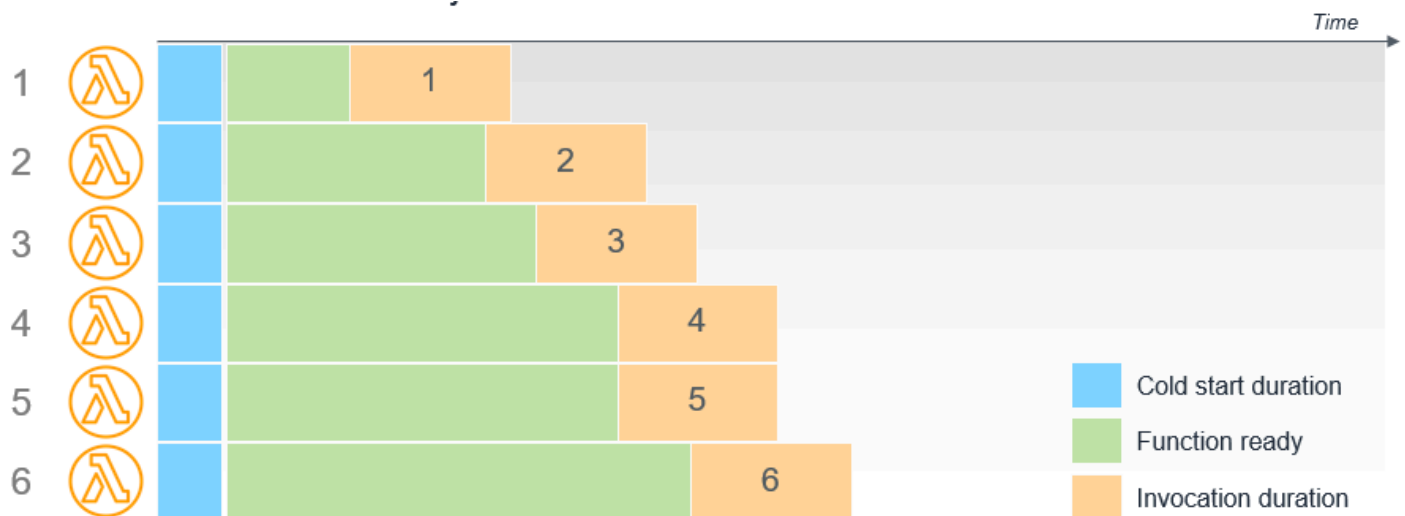

After the invocation completes, the execution environment is frozen. To improve resource management and performance, Lambda retains the execution environment for a period of time. During this time, if another request arrives for the same function, Lambda can reuse the environment. This second request typically finishes more quickly, since the execution environment is already fully set up. This is called a “warm start”.

Cold starts typically occur in under 1% of invocations. The duration of a cold start varies from under 100 ms to over 1 second. In general, cold starts are typically more common in development and test functions than production workloads. This is because development and test functions are usually invoked less frequently.

Reducing cold starts with Provisioned Concurrency

If you need predictable function start times for your workload, [provisioned concurrency](#) is the recommended solution to ensure the lowest possible latency. This feature pre-initializes execution environments, reducing cold starts.

For example, a function with a provisioned concurrency of 6 has 6 execution environments pre-warmed.

Optimizing static initialization

Static initialization happens before the handler code starts running in a function. This is the initialization code that you provide, that is outside of the main handler. This code is often used to import libraries and dependencies, set up configurations, and initialize connections to other services.

The following Python example shows importing, and configuring modules, and creating the Amazon S3 client during the initialization phase, before the `lambda_handler` function runs during invoke.

```
import os
import json
```

```
import cv2
import logging
import boto3

s3 = boto3.client('s3')
logger = logging.getLogger()
logger.setLevel(logging.INFO)

def lambda_handler(event, context):

    # Handler logic...
```

The largest contributor of latency before function execution comes from initialization code. This code runs when a new execution environment is created for the first time. The initialization code is not run again if an invocation uses a warm execution environment. Factors that affect initialization code latency include:

- The size of the function package, in terms of imported libraries and dependencies, and Lambda layers.
- The amount of code and initialization work.
- The performance of libraries and other services in setting up connections and other resources.

There are a number of steps that developers can take to optimize static initialization latency. If a function has many objects and connections, you may be able to rearchitect a single function into multiple, specialized functions. These are individually smaller and each have less initialization code.

It's important that functions only import the libraries and dependencies that they need. For example, if you only use Amazon DynamoDB in the AWS SDK, you can require an individual service instead of the entire SDK. Compare the following three examples:

```
// Instead of const AWS = require('aws-sdk'), use:
const DynamoDB = require('aws-sdk/clients/dynamodb')

// Instead of const AWSXRay = require('aws-xray-sdk'), use:
const AWSXRay = require('aws-xray-sdk-core')

// Instead of const AWS = AWSXRay.captureAWS(require('aws-sdk')), use:
const dynamodb = new DynamoDB.DocumentClient()
AWSXRay.captureAWSClient(dynamodb.service)
```

Static initialization is also often the best place to open database connections to allow a function to reuse connections over multiple invocations to the same execution environment. However, you may have large numbers of objects that are only used in certain execution paths in your function. In this case, you can lazily load variables in the global scope to reduce the static initialization duration.

Avoid global variables for context-specific information. If your function has a global variable that is used only for the lifetime of a single invocation and is reset for the next invocation, use a variable scope that is local to the handler. Not only does this prevent global variable leaks across invocations, it also improves the static initialization performance.

Creating event-driven architectures with Lambda

An event is anything that triggers a Lambda function to run. Events can trigger a Lambda function in two ways: through direct invocation (push) and event source mappings (pull).

Many AWS services can directly invoke your Lambda functions. These services *push* events to your Lambda function. Events that trigger functions can be almost anything, from an HTTP request through API Gateway, a schedule managed by an EventBridge rule, an AWS IoT event, or an Amazon S3 event. With event source mapping, Lambda actively fetches (or *pulls*) events from a queue or stream. You configure Lambda to check for events from a supported service, and Lambda handles the polling and invocation of your function.

When passed to your function, events are structured in JSON format. The JSON structure varies depending on the service that generates it and the event type. While standard Lambda function invocations can last up to 15 minutes (or up to one year with [durable functions](#)), Lambda is best-suited for short invocations that last one second or less. This is particularly true of event-driven architectures, where each Lambda function is treated as a microservice responsible for performing a narrow set of specific instructions.

Note

Event-driven architectures communicate across different systems using networks, which introduce variable latency. For workloads that require very low latency, such as real-time trading systems, this design might not be the best choice. However, for highly scalable and available workloads, or those with unpredictable traffic patterns, event-driven architectures can provide an effective way to meet these demands.

Topics

- [Benefits of event-driven architectures](#)
- [Trade-offs of event-driven architectures](#)
- [Anti-patterns in Lambda-based event-driven applications](#)

Benefits of event-driven architectures

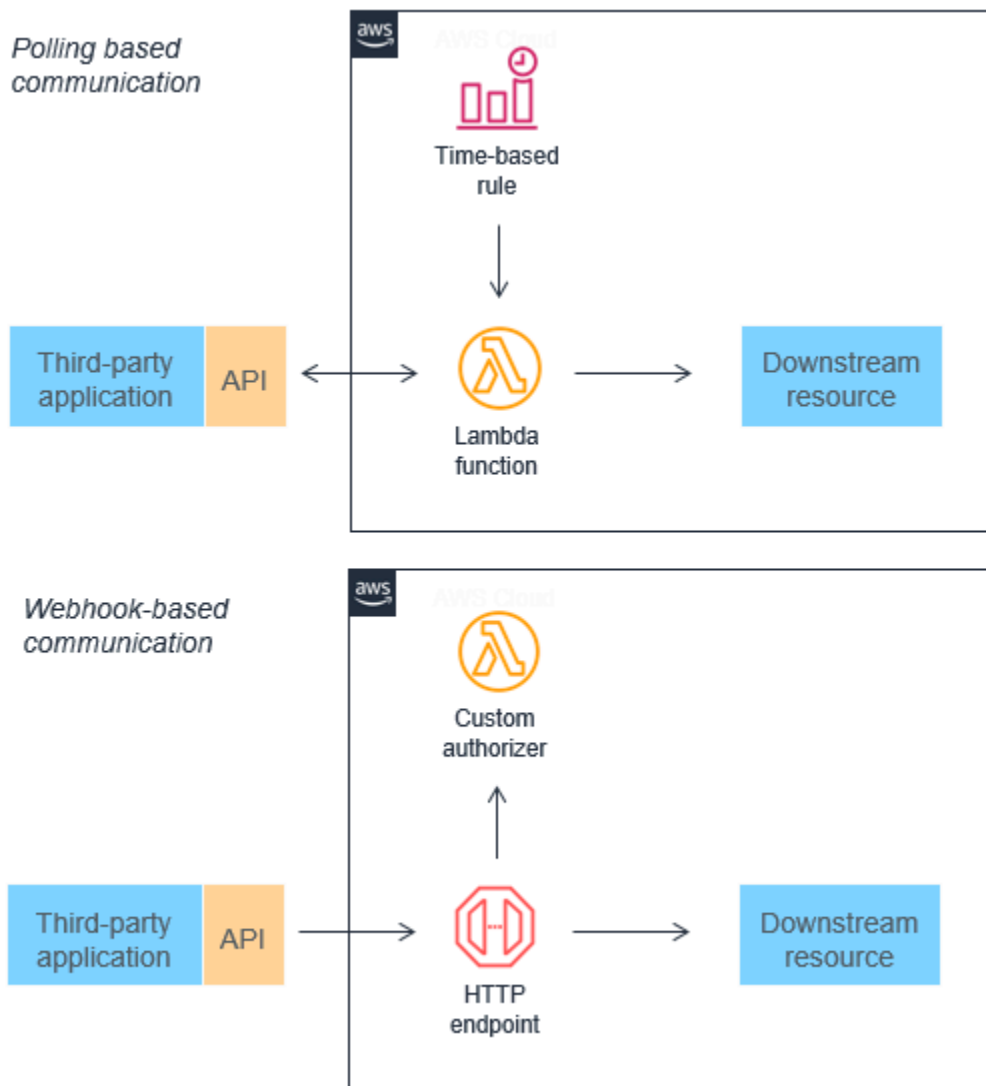

Lambda supports two methods of invocation in event-driven architectures:

1. Direct invocation (push method): AWS services trigger Lambda functions directly. For example:
 - Amazon S3 triggers a function when a file is uploaded
 - API Gateway triggers a function when it receives an HTTP request
2. Event source mapping (pull method): Lambda retrieves events and invokes functions. For example:
 - Lambda retrieves messages from an Amazon SQS queue and invokes a function
 - Lambda reads records from a DynamoDB stream and invokes a function

Both methods contribute to the benefits of event-driven architectures, as described below.

Replacing polling and webhooks with events

Many traditional architectures use polling and webhook mechanisms to communicate state between different components. Polling can be highly inefficient for fetching updates since there is a lag between new data becoming available and synchronization with downstream services. Webhooks are not always supported by other microservices that you want to integrate with. They might also require custom authorization and authentication configurations. In both cases, these integration methods are challenging to scale on-demand without additional work by development teams.

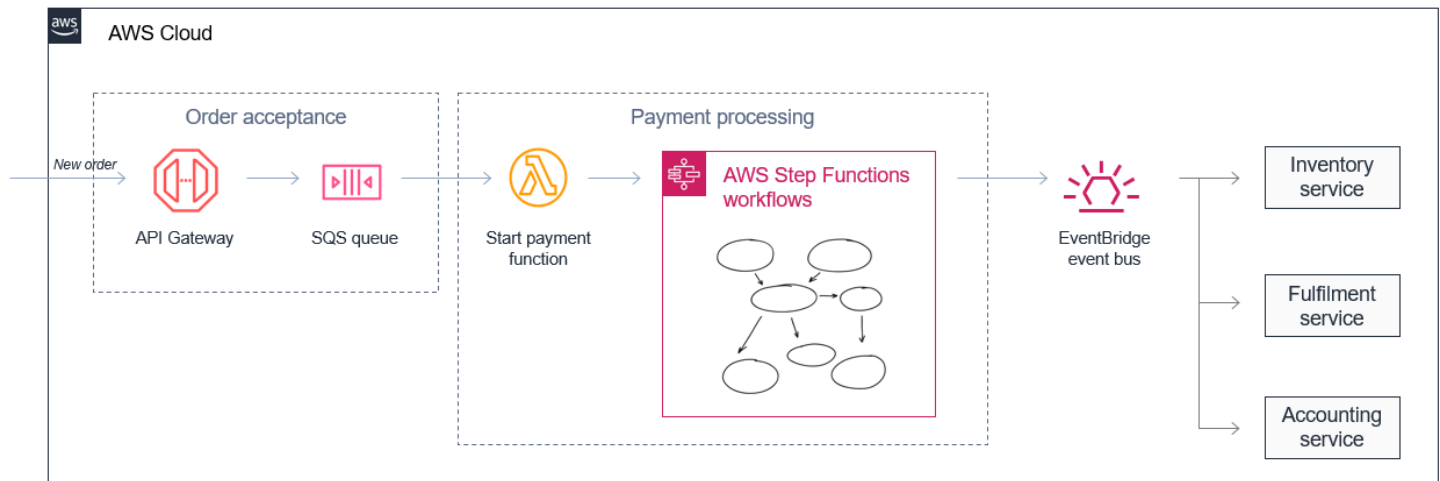

Both of these mechanisms can be replaced by events, which can be filtered, routed, and pushed downstream to consuming microservices. This approach can result in less bandwidth consumption, CPU utilization, and potentially lower cost. These architectures can also reduce complexity, since each functional unit is smaller and there is often less code.

Event-driven architectures can also make it easier to design near-real-time systems, helping organizations move away from batch-based processing. Events are generated at the time when state in the application changes, so the custom code of a microservice should be designed to handle the processing of a single event. Since scaling is handled by the Lambda service, this architecture can handle significant increases in traffic without changing custom code. As events scale up, so does the compute layer that processes events.

Reducing complexity

Microservices enable developers and architects to simplify complex workflows. For example, an ecommerce monolith can be broken down into order acceptance and payment processes with separate inventory, fulfillment and accounting services. What might be complex to manage and orchestrate in a monolith becomes a series of decoupled services that communicate asynchronously with events.

This approach also makes it possible to assemble services that process data at different rates. In this case, an order acceptance microservice can store high volumes of incoming orders by buffering the messages in an Amazon SQS queue.

A payment processing service, which is typically slower due to the complexity of handling payments, can take a steady stream of messages from the Amazon SQS queue. It can orchestrate complex retry and error handling logic using AWS Step Functions, and coordinate active payment workflows for hundreds of thousands of orders.

Alternative approach: For orchestration using standard programming languages, you can use [Lambda durable functions](#). Durable functions let you write the order acceptance, payment processing, and notification logic in code with automatic checkpointing and retry. This approach

works well when the workflow primarily involves Lambda functions and you prefer keeping orchestration logic in code.

Improving scalability and extensibility

Microservices generate events that are typically published to messaging services like Amazon SNS and Amazon SQS. These behave like an elastic buffer between microservices and help handle scaling when traffic increases. Services like Amazon EventBridge can then filter and route messages depending upon the content of the event, as defined in rules. As a result, event-based applications can be more scalable and offer greater redundancy than monolithic applications.

This system is also highly extensible, allowing other teams to extend features and add functionality without impacting the order processing and payment processing microservices. By publishing events using EventBridge, this application integrates with existing systems, such as the inventory microservice, but also enables any future application to integrate as an event consumer. Producers of events have no knowledge of event consumers, which can help simplify the microservice logic.

Trade-offs of event-driven architectures

Variable latency

Unlike monolithic applications, which might process everything within the same memory space on a single device, event-driven applications communicate across networks. This design introduces variable latency. While it's possible to engineer applications to minimize latency, monolithic applications can almost always be optimized for lower latency at the expense of scalability and availability.

Workloads that require consistent low-latency performance, such as high-frequency trading applications in banks or sub-millisecond robotics automation in warehouses, are not good candidates for event-driven architecture.

Eventual consistency

An event represents a change in state, and with many events flowing through different services in an architecture at any given point of time, such workloads are often [eventually consistent](#). This makes it more complex to process transactions, handle duplicates, or determine the exact overall state of a system.

Some workloads contain a combination of requirements that are eventually consistent (for example, total orders in the current hour) or strongly consistent (for example, current inventory).

For workloads needing strong data consistency, there are architecture patterns to support this. For example:

- DynamoDB can provide [strongly consistent reads](#), sometimes at a higher latency, consuming a greater throughput than the default mode. DynamoDB can also [support transactions](#) to help maintain data consistency.
- You can use Amazon RDS for features needing [ACID properties](#), though relational databases are generally less scalable than NoSQL databases like DynamoDB. [Amazon RDS Proxy](#) can help manage connection pooling and scaling from ephemeral consumers like Lambda functions.

Event-based architectures are usually designed around individual events instead of large batches of data. Generally, workflows are designed to manage the steps of an individual event or execution flow instead of operating on multiple events simultaneously. In serverless, real-time event processing is preferred over batch processing: batches should be replaced with many smaller incremental updates. While this can make workloads more available and scalable, it also makes it more challenging for events to have awareness of other events.

Returning values to callers

In many cases, event-based applications are asynchronous. This means that caller services do not wait for requests from other services before continuing with other work. This is a fundamental characteristic of event-driven architectures that enables scalability and flexibility. This means that passing return values or the result of a workflow is more complex than in synchronous execution flows.

Most Lambda invocations in production systems are [asynchronous](#), responding to events from services like Amazon S3 or Amazon SQS. In these cases, the success or failure of processing an event is often more important than returning a value. Features such as [dead letter queues](#) (DLQs) in Lambda are provided to ensure you can identify and retry failed events, without needing to notify the caller.

Debugging across services and functions

Debugging event-driven systems is also different compared to a monolithic application. With different systems and services passing events, it's not possible to record and reproduce the exact state of multiple services when errors occur. Since each service and function invocation has separate log files, it can be more complicated to determine what happened to a specific event that caused an error.

There are three important requirements for building a successful debugging approach in event-driven systems. First, a robust logging system is critical, and this is provided across AWS services and embedded in Lambda functions by Amazon CloudWatch. Second, in these systems, it's important to ensure that every event has a transaction identifier that is logged at each step throughout a transaction, to help when searching for logs.

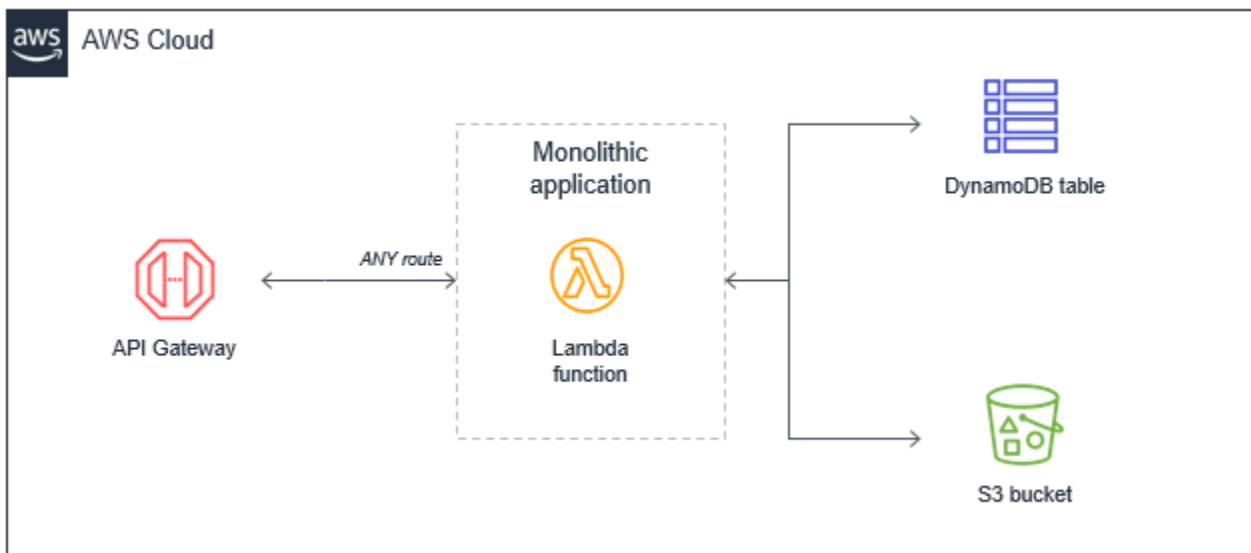

Finally, it's highly recommended to automate the parsing and analysis of logs by using a debugging and monitoring service like AWS X-Ray. This can consume logs across multiple Lambda invocations and services, making it much easier to pinpoint the root cause of issues. See [Troubleshooting walkthrough](#) for in-depth coverage of using X-Ray for troubleshooting.

Anti-patterns in Lambda-based event-driven applications

When building event-driven architectures with Lambda, avoid the following common anti-patterns. These patterns work but can increase costs and complexity.

The Lambda monolith

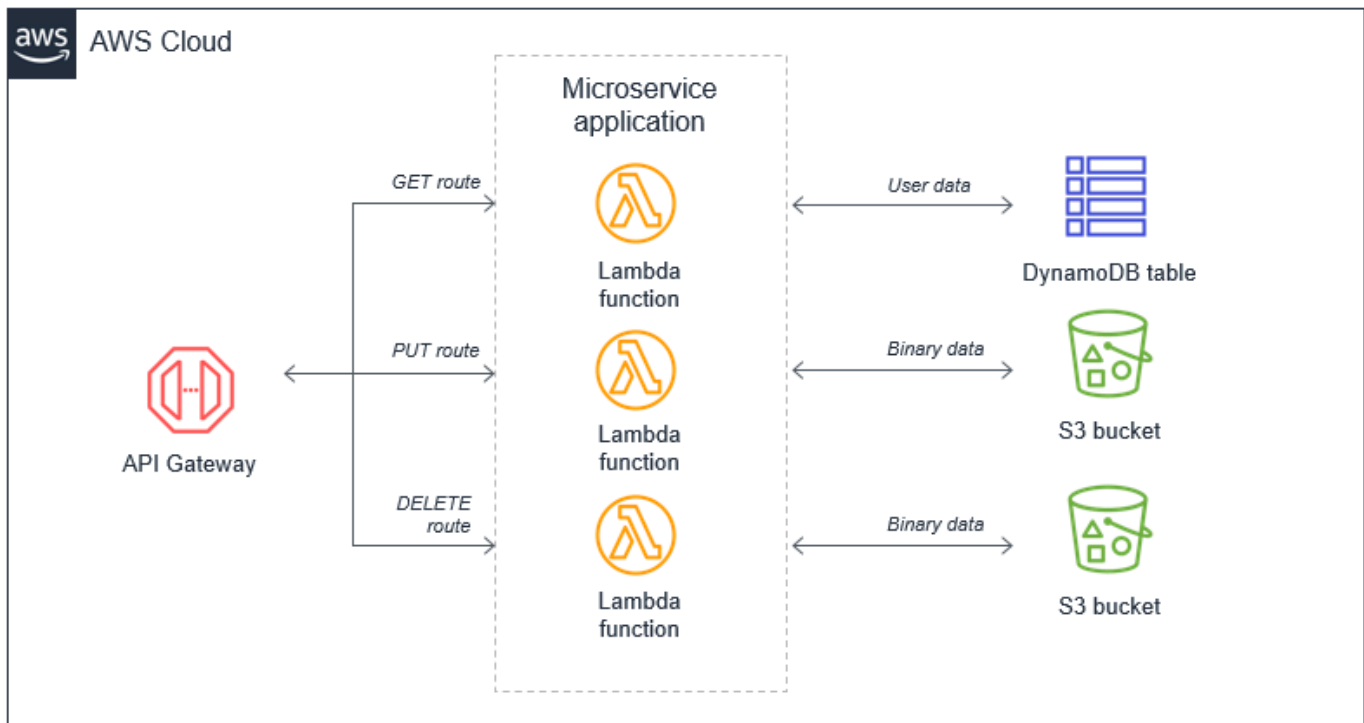

In many applications migrated from traditional servers, such as Amazon EC2 instances or Elastic Beanstalk applications, developers “lift and shift” existing code. Frequently, this results in a single Lambda function that contains all of the application logic that is triggered for all events. For a basic web application, a monolithic Lambda function would handle all API Gateway routes and integrate with all necessary downstream resources.

This approach has several drawbacks:

- **Package size** – The Lambda function might be much larger because it contains all possible code for all paths, which makes it slower for the Lambda service to run.
- **Hard to enforce least privilege** – The function's [execution role](#) must allow permissions to all resources needed for all paths, making the permissions very broad. This is a security concern. Many paths in the functional monolith do not need all the permissions that have been granted.
- **Harder to upgrade** – In a production system, any upgrades to the single function are more risky and could break the entire application. Upgrading a single path in the Lambda function is an upgrade to the entire function.
- **Harder to maintain** – It's more difficult to have multiple developers working on the service since it's a monolithic code repository. It also increases the cognitive burden on developers and makes it harder to create appropriate test coverage for code.
- **Harder to reuse code** – It's harder to separate reusable libraries from monoliths, making code reuse more difficult. As you develop and support more projects, this can make it harder to support the code and scale your team's velocity.
- **Harder to test** – As the lines of code increase, it becomes harder to unit test all the possible combinations of inputs and entry points in the code base. It's generally easier to implement unit testing for smaller services with less code.

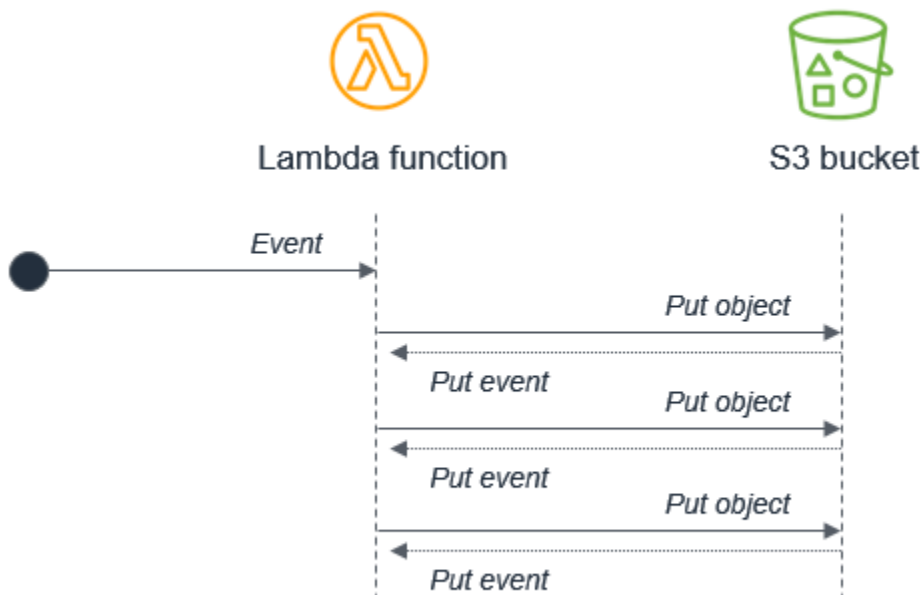

The preferred alternative is to break down the monolithic Lambda function into individual microservices, mapping a single Lambda function to a single, well-defined task. In this simple web application with a few API endpoints, the resulting microservice-based architecture can be based upon the API Gateway routes.

Recursive patterns that cause runaway Lambda functions

AWS services generate events that invoke Lambda functions, and Lambda functions can send messages to AWS services. Generally, the service or resource that invokes a Lambda function should be different to the service or resource that the function outputs to. Failure to manage this can result in infinite loops.

For example, a Lambda function writes an object to an Amazon S3 object, which in turn invokes the same Lambda function via a put event. The invocation causes a second object to be written to the bucket, which invokes the same Lambda function:

While the potential for infinite loops exists in most programming languages, this anti-pattern has the potential to consume more resources in serverless applications. Both Lambda and Amazon S3 automatically scale based upon traffic, so the loop can cause Lambda to scale to consume all available concurrency and Amazon S3 will continue to write objects and generate more events for Lambda.

This example uses S3, but the risk of recursive loops also exists in Amazon SNS, Amazon SQS, DynamoDB, and other services. You can use [recursive loop detection](#) to find and avoid this anti-pattern.

Lambda functions calling Lambda functions

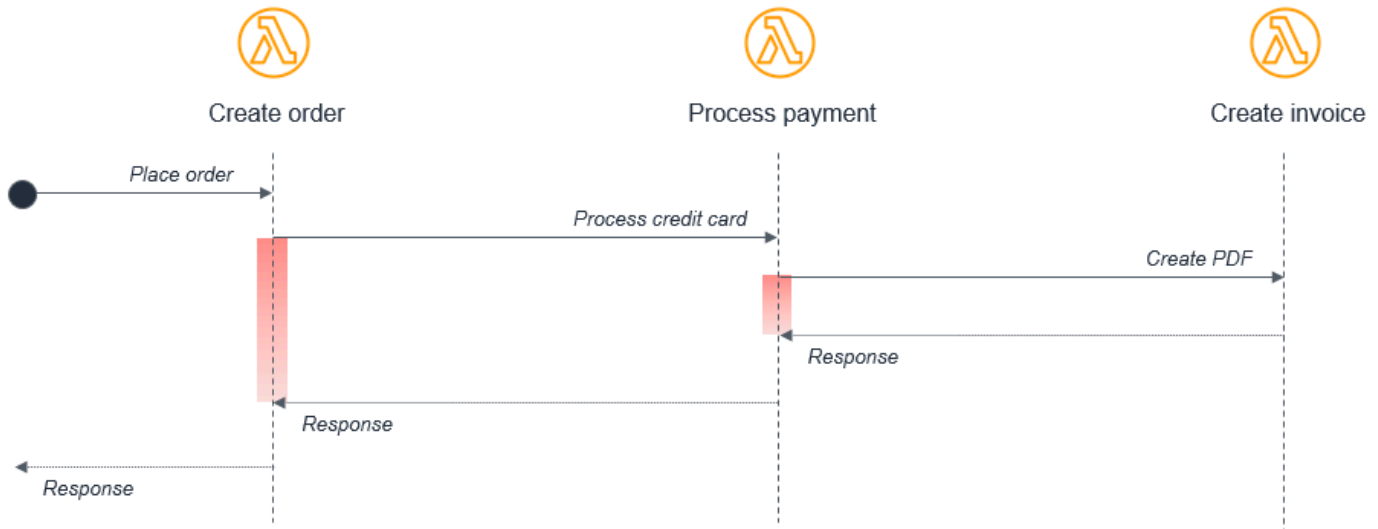

Functions enable encapsulation and code re-use. Most programming languages support the concept of code synchronously calling functions within a code base. In this case, the caller waits until the function returns a response.

Note

While Lambda functions directly calling other Lambda functions is generally an anti-pattern due to cost and complexity concerns, this doesn't apply to [durable functions](#), which are specifically designed to orchestrate multi-step workflows by invoking other functions.

When this happens on a traditional server or virtual instance, the operating system scheduler switches to other available work. Whether the CPU runs at 0% or 100% does not affect the overall cost of the application, since you are paying for the fixed cost of owning and operating a server.

This model often does not adapt well to serverless development. For example, consider a simple ecommerce application consisting of three Lambda functions that process an order:

In this case, the *Create order* function calls the *Process payment* function, which in turn calls the *Create invoice* function. While this synchronous flow might work within a single application on a server, it introduces several avoidable problems in a distributed serverless architecture:

- **Cost** – With Lambda, you pay for the duration of an invocation. In this example, while the *Create invoice* function runs, two other functions are also running in a wait state, shown in red on the diagram.
- **Error handling** – In nested invocations, error handling can become much more complex. For example, an error in *Create invoice* might require the *Process payment* function to reverse the charge, or it might instead retry the *Create invoice* process.
- **Tight coupling** – Processing a payment typically takes longer than creating an invoice. In this model, the availability of the entire workflow is limited by the slowest function.
- **Scaling** – The [concurrency](#) of all three functions must be equal. In a busy system, this uses more concurrency than would otherwise be needed.

In serverless applications, there are two common approaches to avoid this pattern. First, use an Amazon SQS queue between Lambda functions. If a downstream process is slower than an upstream process, the queue durably persists messages and decouples the two functions. In this

example, the *Create order* function would publish a message to an Amazon SQS queue, and the *Process payment* function consumes messages from the queue.

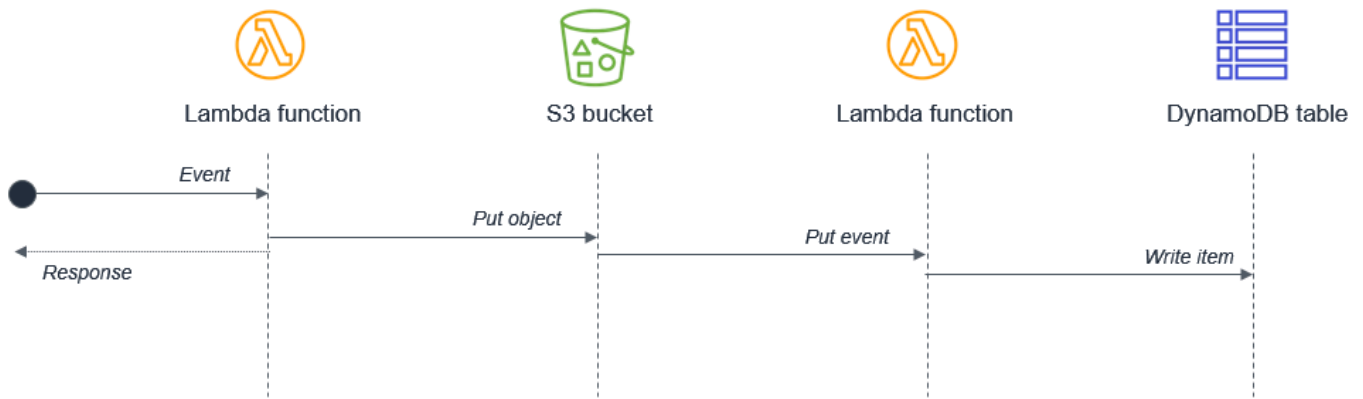

The second approach is to use AWS Step Functions. For complex processes with multiple types of failure and retry logic, Step Functions can help reduce the amount of custom code needed to orchestrate the workflow. As a result, Step Functions orchestrates the work and robustly handles errors and retries, and the Lambda functions contain only business logic.

Synchronous waiting within a single Lambda function

Make sure that any potentially concurrent activities are not scheduled synchronously within a single Lambda function. For example, a Lambda function might write to an S3 bucket and then write to a DynamoDB table:

In this design, wait times are compounded because the activities are sequential. In cases where the second task depends on the completion of the first task, you can reduce the total waiting time and the cost of execution by have two separate Lambda functions:

In this design, the first Lambda function responds immediately after putting the object to the Amazon S3 bucket. The S3 service invokes the second Lambda function, which then writes data to the DynamoDB table. This approach minimizes the total wait time in the Lambda function executions.

Designing Lambda applications

A well-architected event-driven application uses a combination of AWS services and custom code to process and manage requests and data. This chapter focuses on Lambda-specific topics in application design. There are many important considerations for serverless architects when designing applications for busy production systems.

Many of the best practices that apply to software development and distributed systems also apply to serverless application development. The overall goal is to develop workloads that are:

- **Reliable** – offering your end users a high level of availability. AWS serverless services are reliable because they are also designed for failure.
- **Durable** – providing storage options that meet the durability needs of your workload.
- **Secure** – following best practices and using the tools provided to secure access to workloads and limit the blast radius.
- **Performant** – using computing resources efficiently and meeting the performance needs of your end users.
- **Cost-efficient**– designing architectures that avoid unnecessary cost that can scale without overspending, and also be decommissioned without significant overhead.

The following design principles can help you build workloads that meet these goals. Not every principle may apply to every architecture, but they should guide you in general architecture decisions.

Topics

- [Use services instead of custom code](#)
- [Understand Lambda abstraction levels](#)
- [Implement statelessness in functions](#)
- [Minimize coupling](#)
- [Build for on-demand data instead of batches](#)
- [Choose an orchestration option for complex workflows](#)
- [Implement idempotency](#)
- [Use multiple AWS accounts for managing quotas](#)

Use services instead of custom code

Serverless applications usually comprise several AWS services, integrated with custom code run in Lambda functions. While Lambda can be integrated with most AWS services, the services most commonly used in serverless applications are:

Category	AWS service
Compute	AWS Lambda
Data storage	Amazon S3
	Amazon DynamoDB
	Amazon RDS
API	Amazon API Gateway
Application integration	Amazon EventBridge
	Amazon SNS
	Amazon SQS
Orchestration	Lambda durable functions
	AWS Step Functions
Streaming data and analytics	Amazon Data Firehose

Note

Many serverless services provide replication and support for multiple Regions, including DynamoDB and Amazon S3. Lambda functions can be deployed in multiple Regions as part of a deployment pipeline, and API Gateway can be configured to support this configuration. See this [example architecture](#) that shows how this can be achieved.

There are many well-established, common patterns in distributed architectures that you can build yourself or implement using AWS services. For most customers, there is little commercial value in

investing time to develop these patterns from scratch. When your application needs one of these patterns, use the corresponding AWS service:

Pattern	AWS service
Queue	Amazon SQS
Event bus	Amazon EventBridge
Publish/subscribe (fan-out)	Amazon SNS
Orchestration	Lambda durable functions AWS Step Functions
API	Amazon API Gateway
Event streams	Amazon Kinesis

These services are designed to integrate with Lambda and you can use infrastructure as code (IaC) to create and discard resources in the services. You can use any of these services via the [AWS SDK](#) without needing to install applications or configure servers. Becoming proficient with using these services via code in your Lambda functions is an important step to producing well-designed serverless applications.

Understand Lambda abstraction levels

The Lambda service limits your access to the underlying operating systems, hypervisors, and hardware running your Lambda functions. The service continuously improves and changes infrastructure to add features, reduce cost and make the service more performant. Your code should assume no knowledge of how Lambda is architected and assume no hardware affinity.

Similarly, Lambda's integrations with other services are managed by AWS, with only a small number of configuration options exposed to you. For example, when API Gateway and Lambda interact, there is no concept of load balancing since it is entirely managed by the services. You also have no direct control over which [Availability Zones](#) the services use when invoking functions at any point in time, or how Lambda determines when to scale up or down the number of execution environments.

This abstraction helps you focus on the integration aspects of your application, the flow of data, and the business logic where your workload provides value to your end users. Allowing the services to manage the underlying mechanics helps you develop applications more quickly with less custom code to maintain.

Implement statelessness in functions

For standard Lambda functions, you should assume that the environment exists only for a single invocation. The function should initialize any required state when it is first started. For example, your function may require fetching data from a DynamoDB table. It should commit any permanent data changes to a durable store such as Amazon S3, DynamoDB, or Amazon SQS before exiting. It should not rely on any existing data structures or temporary files, or any internal state that would be managed by multiple invocations.

When using Durable Functions, state is automatically preserved between invocations, eliminating the need to manually persist state to external storage. However, you should still follow stateless principles for any data not explicitly managed through the `DurableContext`.

To initialize database connections and libraries, or load state, you can take advantage of [static initialization](#). Since execution environments are reused where possible to improve performance, you can amortize the time taken to initialize these resources over multiple invocations. However, you should not store any variables or data used in the function within this global scope.

Minimize coupling

Most architectures should prefer many, shorter functions over fewer, larger ones. The purpose of each function should be to handle the event passed into the function, with no knowledge or expectations of the overall workflow or volume of transactions. This makes the function agnostic to the source of the event with minimal coupling to other services.

Any global-scope constants that change infrequently should be implemented as environment variables to allow updates without deployments. Any secrets or sensitive information should be stored in [AWS Systems Manager Parameter Store](#) or [AWS Secrets Manager](#) and loaded by the function. Since these resources are account-specific, you can create build pipelines across multiple accounts. The pipelines load the appropriate secrets per environment, without exposing these to developers or requiring any code changes.

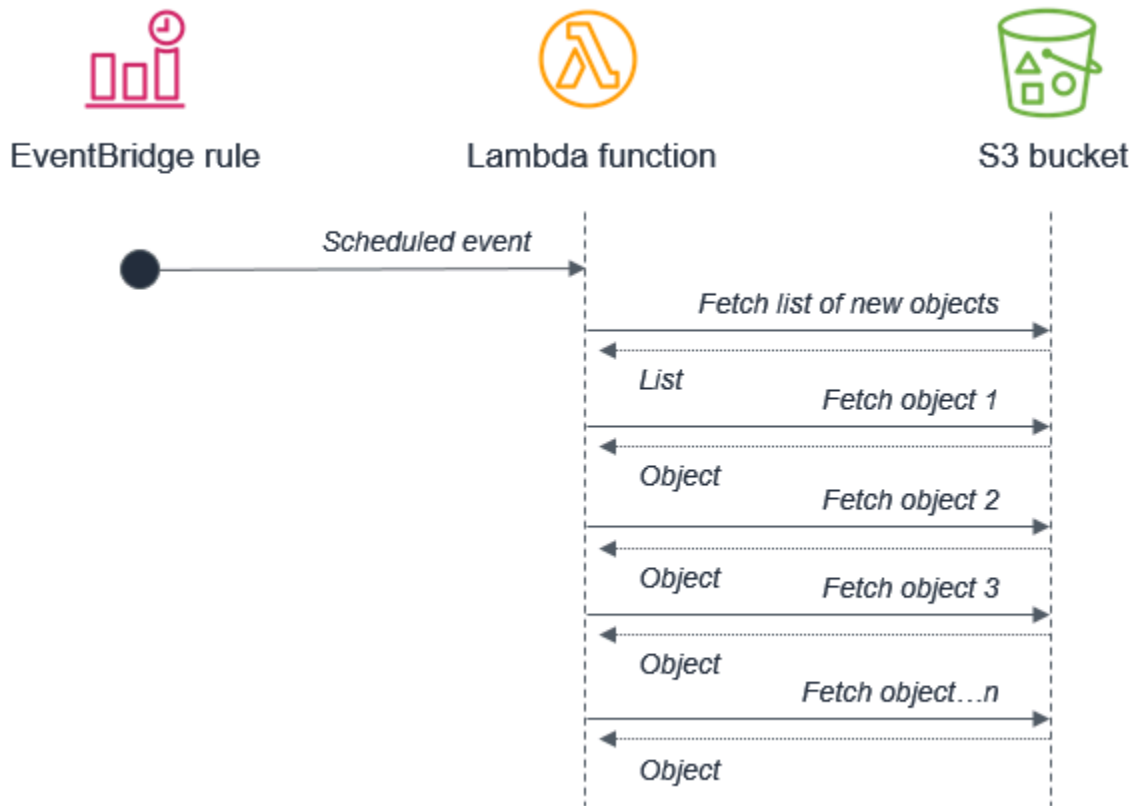

Build for on-demand data instead of batches

Many traditional systems are designed to run periodically and process batches of transactions that have built up over time. For example, a banking application may run every hour to process ATM transactions into central ledgers. In Lambda-based applications, the custom processing should be triggered by every event, allowing the service to scale up concurrency as needed, to provide near-real time processing of transactions.

While standard Lambda functions are limited to 15 minutes of execution time, Durable Functions can run for up to one year, making them suitable for longer-running processing needs. However, you should still prefer event-driven processing over batch processing when possible.

While you can run [cron](#) tasks in serverless applications [by using scheduled expressions](#) for rules in Amazon EventBridge, these should be used sparingly or as a last-resort. In any scheduled task that processes a batch, there is the potential for the volume of transactions to grow beyond what can be processed within the 15-minute Lambda duration limit. If the limitations of external systems force you to use a scheduler, you should generally schedule for the shortest reasonable recurring time period.

For example, it's not best practice to use a batch process that triggers a Lambda function to fetch a list of new Amazon S3 objects. This is because the service may receive more new objects in between batches than can be processed within a 15-minute Lambda function.

Instead, Amazon S3 should invoke the Lambda function each time a new object is put into the bucket. This approach is significantly more scalable and works in near-real time.

Choose an orchestration option for complex workflows

Workflows that involve branching logic, different types of failure models, and retry logic typically use an orchestrator to keep track of the state of the overall execution. Don't build ad-hoc orchestration in standard Lambda functions. This results in tight coupling, complex routing code, and no automatic state recovery.

Instead, use one of these purpose-built orchestration options:

- **[Lambda durable functions](#)**: Application-centric orchestration using standard programming languages with automatic checkpointing, built-in retry, and execution recovery. Ideal for developers who prefer keeping workflow logic in code alongside business logic within Lambda.
- **[AWS Step Functions](#)**: Visual workflow orchestration with native integrations to 220+ AWS services. Ideal for multi-service coordination, zero-maintenance infrastructure, and visual workflow design.

For guidance on choosing between these options, see [Durable functions or Step Functions](#).

With [Step Functions](#), you use state machines to manage orchestration. This extracts the error handling, routing, and branching logic from your code, replacing it with state machines declared using JSON. Apart from making workflows more robust and observable, you can also add versioning to workflows and make the state machine a codified resource that you can add to a code repository.

It's common for simpler workflows in Lambda functions to become more complex over time. When operating a production serverless application, it's important to identify when this is happening, so you can migrate this logic to a state machine or durable function.

Implement idempotency

AWS serverless services, including Lambda, are fault-tolerant and designed to handle failures. For example, if a service invokes a Lambda function and there is a service disruption, Lambda invokes your function in a different Availability Zone. If your function throws an error, Lambda retries the invocation.

Since the same event may be received more than once, functions should be designed to be [idempotent](#). This means that receiving the same event multiple times does not change the result beyond the first time the event was received.

You can implement idempotency in Lambda functions by using a DynamoDB table to track recently processed identifiers to determine if the transaction has already been handled previously. The DynamoDB table usually implements a [Time To Live \(TTL\)](#) value to expire items to limit the storage space used.

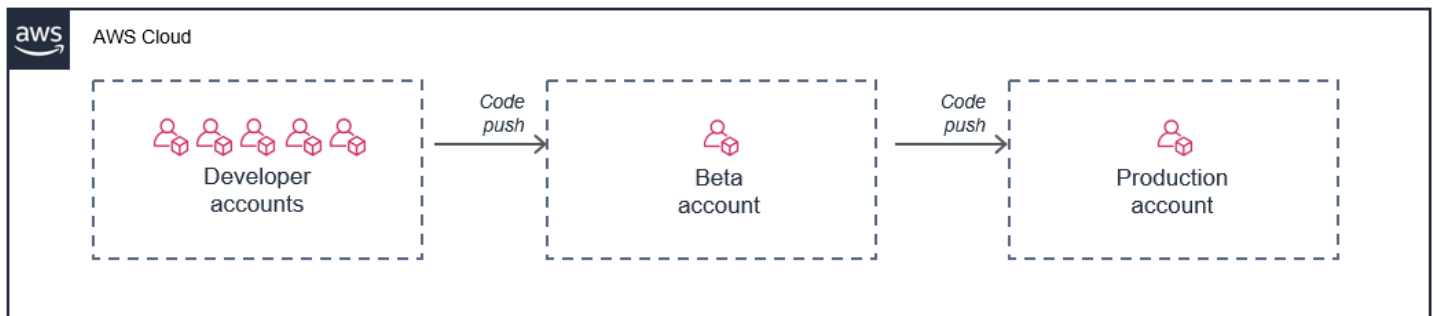

Use multiple AWS accounts for managing quotas

Many [service quotas](#) in AWS are set at the account level. This means that as you add more workloads, you can quickly exhaust your limits.

An effective way to solve this issue is to use multiple AWS accounts, dedicating each workload to its own account. This prevents quotas from being shared with other workloads or non-production resources.

In addition, by using [AWS Organizations](#), you can centrally manage the billing, compliance, and security of these accounts. You can attach policies to groups of accounts to avoid custom scripts and manual processes.

One common approach is to provide each developer with an AWS account, and then use separate accounts for a beta deployment stage and production:

In this model, each developer has their own set of limits for the account, so their usage does not impact your production environment. This approach also allows developers to test Lambda functions locally on their development machines against live cloud resources in their individual accounts.

Create your first Lambda function

To get started with Lambda, use the Lambda console to create a function. In a few minutes, you can create and deploy a function and test it in the console.

As you carry out the tutorial, you'll learn some fundamental Lambda concepts, like how to pass arguments to your function using the Lambda *event object*. You'll also learn how to return log outputs from your function, and how to view your function's invocation logs in Amazon CloudWatch Logs.

To keep things simple, you create your function using either the Python or Node.js runtime. With these interpreted languages, you can edit function code directly in the console's built-in code editor. With compiled languages like Java and C#, you must create a deployment package on your local build machine and upload it to Lambda. To learn about deploying functions to Lambda using other runtimes, see the links in the [the section called "Next steps"](#) section.

Tip

To learn how to build **serverless solutions**, check out the [Serverless Developer Guide](#).

Prerequisites

Sign up for an AWS account

If you do not have an AWS account, complete the following steps to create one.

To sign up for an AWS account

1. Open <https://portal.aws.amazon.com/billing/signup>.
2. Follow the online instructions.

Part of the sign-up procedure involves receiving a phone call or text message and entering a verification code on the phone keypad.

When you sign up for an AWS account, an *AWS account root user* is created. The root user has access to all AWS services and resources in the account. As a security best practice, assign administrative access to a user, and use only the root user to perform [tasks that require root user access](#).

AWS sends you a confirmation email after the sign-up process is complete. At any time, you can view your current account activity and manage your account by going to <https://aws.amazon.com/> and choosing **My Account**.

Create a user with administrative access

After you sign up for an AWS account, secure your AWS account root user, enable AWS IAM Identity Center, and create an administrative user so that you don't use the root user for everyday tasks.

Secure your AWS account root user

1. Sign in to the [AWS Management Console](#) as the account owner by choosing **Root user** and entering your AWS account email address. On the next page, enter your password.

For help signing in by using root user, see [Signing in as the root user](#) in the *AWS Sign-In User Guide*.

2. Turn on multi-factor authentication (MFA) for your root user.

For instructions, see [Enable a virtual MFA device for your AWS account root user \(console\)](#) in the *IAM User Guide*.

Create a user with administrative access

1. Enable IAM Identity Center.

For instructions, see [Enabling AWS IAM Identity Center](#) in the *AWS IAM Identity Center User Guide*.

2. In IAM Identity Center, grant administrative access to a user.

For a tutorial about using the IAM Identity Center directory as your identity source, see [Configure user access with the default IAM Identity Center directory](#) in the *AWS IAM Identity Center User Guide*.

Sign in as the user with administrative access

- To sign in with your IAM Identity Center user, use the sign-in URL that was sent to your email address when you created the IAM Identity Center user.

For help signing in using an IAM Identity Center user, see [Signing in to the AWS access portal](#) in the *AWS Sign-In User Guide*.

Assign access to additional users

1. In IAM Identity Center, create a permission set that follows the best practice of applying least-privilege permissions.

For instructions, see [Create a permission set](#) in the *AWS IAM Identity Center User Guide*.

2. Assign users to a group, and then assign single sign-on access to the group.

For instructions, see [Add groups](#) in the *AWS IAM Identity Center User Guide*.

Create a Lambda function with the console

In this example, your function takes a JSON object containing two integer values labeled "length" and "width". The function multiplies these values to calculate an area and returns this as a JSON string.

Your function also prints the calculated area, along with the name of its CloudWatch log group. Later in the tutorial, you'll learn to use [CloudWatch Logs](#) to view records of your functions' invocation.

To create a Hello world Lambda function with the console

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Select **Author from scratch**.
4. In the **Basic information** pane, for **Function name**, enter **myLambdaFunction**.
5. For **Runtime**, choose either **Node.js 24** or **Python 3.14**.
6. Leave **architecture** set to **x86_64**, and then choose **Create function**.

In addition to a simple function that returns the message `Hello from Lambda!`, Lambda also creates an [execution role](#) for your function. An execution role is an AWS Identity and Access Management (IAM) role that grants a Lambda function permission to access AWS services and

resources. For your function, the role that Lambda creates grants basic permissions to write to CloudWatch Logs.

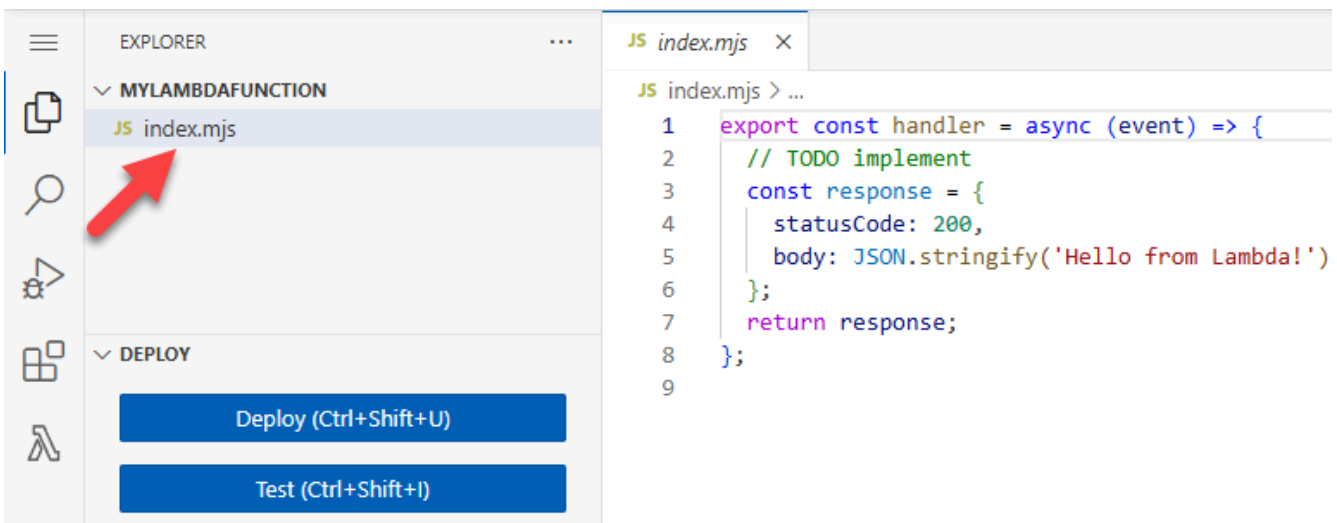

Use the console's built-in code editor to replace the Hello world code that Lambda created with your own function code.

Node.js

To modify the code in the console

1. Choose the **Code** tab.

In the console's built-in code editor, you should see the function code that Lambda created. If you don't see the **index.mjs** tab in the code editor, select **index.mjs** in the file explorer as shown on the following diagram.

2. Paste the following code into the **index.mjs** tab, replacing the code that Lambda created.

```
export const handler = async (event, context) => {

  const length = event.length;
  const width = event.width;
  let area = calculateArea(length, width);
  console.log(`The area is ${area}`);

  console.log('CloudWatch log group: ', context.logGroupName);

  let data = {
    "area": area,
  };
};
```

```
    return JSON.stringify(data);

    function calculateArea(length, width) {
        return length * width;
    }
};
```

3. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Understanding your function code

Before you move to the next step, let's take a moment to look at the function code and understand some key Lambda concepts.

- The Lambda handler:

Your Lambda function contains a Node.js function named `handler`. A Lambda function in Node.js can contain more than one Node.js function, but the *handler* function is always the entry point to your code. When your function is invoked, Lambda runs this method.

When you created your Hello world function using the console, Lambda automatically set the name of the handler method for your function to `handler`. Be sure not to edit the name of this Node.js function. If you do, Lambda won't be able to run your code when you invoke your function.

To learn more about the Lambda handler in Node.js, see [the section called "Handler"](#).

- The Lambda event object:

The function `handler` takes two arguments, `event` and `context`. An *event* in Lambda is a JSON formatted document that contains data for your function to process.

If your function is invoked by another AWS service, the event object contains information about the event that caused the invocation. For example, if your function is invoked when

an object is uploaded to an Amazon Simple Storage Service (Amazon S3) bucket, the event contains the name of the bucket and the object key.

In this example, you'll create an event in the console by entering a JSON formatted document with two key-value pairs.

- The Lambda context object:

The second argument that your function takes is context. Lambda passes the *context object* to your function automatically. The context object contains information about the function invocation and execution environment.

You can use the context object to output information about your function's invocation for monitoring purposes. In this example, your function uses the `logGroupName` parameter to output the name of its CloudWatch log group.

To learn more about the Lambda context object in Node.js, see [the section called "Context"](#).

- Logging in Lambda:

With Node.js, you can use console methods like `console.log` and `console.error` to send information to your function's log. The example code uses `console.log` statements to output the calculated area and the name of the function's CloudWatch Logs group. You can also use any logging library that writes to `stdout` or `stderr`.

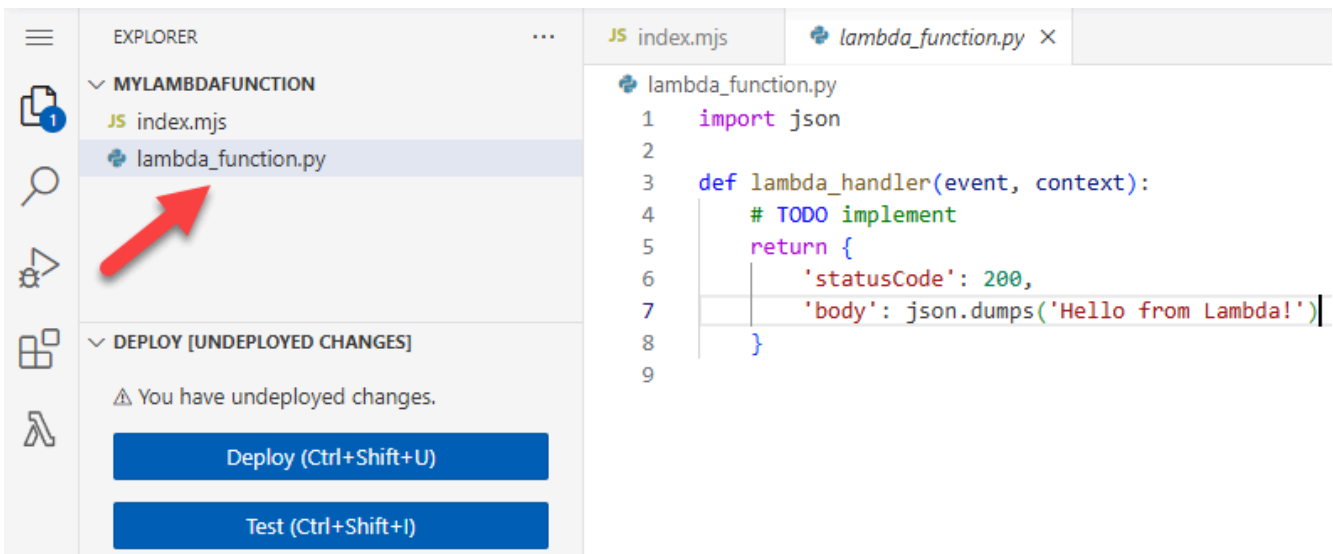

To learn more, see [the section called "Logging"](#). To learn about logging in other runtimes, see the 'Building with' pages for the runtimes you're interested in.

Python

To modify the code in the console

1. Choose the **Code** tab.

In the console's built-in code editor, you should see the function code that Lambda created. If you don't see the **lambda_function.py** tab in the code editor, select **lambda_function.py** in the file explorer as shown on the following diagram.

2. Paste the following code into the **lambda_function.py** tab, replacing the code that Lambda created.

```
import json
import logging

logger = logging.getLogger()
logger.setLevel(logging.INFO)

def lambda_handler(event, context):

    # Get the length and width parameters from the event object. The
    # runtime converts the event object to a Python dictionary
    length = event['length']
    width = event['width']

    area = calculate_area(length, width)
    print(f"The area is {area}")

    logger.info(f"CloudWatch logs group: {context.log_group_name}")

    # return the calculated area as a JSON string
    data = {"area": area}
    return json.dumps(data)

def calculate_area(length, width):
    return length*width
```

3. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Understanding your function code

Before you move to the next step, let's take a moment to look at the function code and understand some key Lambda concepts.

- The Lambda handler:

Your Lambda function contains a Python function named `lambda_handler`. A Lambda function in Python can contain more than one Python function, but the *handler* function is always the entry point to your code. When your function is invoked, Lambda runs this method.

When you created your Hello world function using the console, Lambda automatically set the name of the handler method for your function to `lambda_handler`. Be sure not to edit the name of this Python function. If you do, Lambda won't be able to run your code when you invoke your function.

To learn more about the Lambda handler in Python, see [the section called "Handler"](#).

- The Lambda event object:

The function `lambda_handler` takes two arguments, *event* and *context*. An *event* in Lambda is a JSON formatted document that contains data for your function to process.

If your function is invoked by another AWS service, the event object contains information about the event that caused the invocation. For example, if your function is invoked when an object is uploaded to an Amazon Simple Storage Service (Amazon S3) bucket, the event contains the name of the bucket and the object key.

In this example, you'll create an event in the console by entering a JSON formatted document with two key-value pairs.

- The Lambda context object:

The second argument that your function takes is context. Lambda passes the *context object* to your function automatically. The context object contains information about the function invocation and execution environment.

You can use the context object to output information about your function's invocation for monitoring purposes. In this example, your function uses the `log_group_name` parameter to output the name of its CloudWatch log group.

To learn more about the Lambda context object in Python, see [the section called "Context"](#).

- **Logging in Lambda:**

With Python, you can use either a `print` statement or a Python logging library to send information to your function's log. To illustrate the difference in what's captured, the example code uses both methods. In a production application, we recommend that you use a logging library.

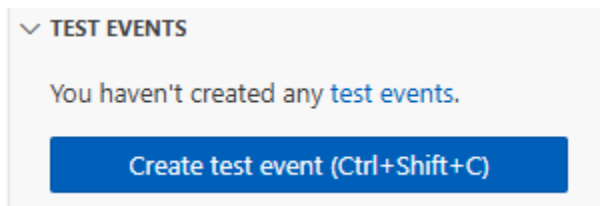

To learn more, see [the section called "Logging"](#). To learn about logging in other runtimes, see the 'Building with' pages for the runtimes you're interested in.

Invoke the Lambda function using the console code editor

To invoke your function using the Lambda console code editor, create a test event to send to your function. The event is a JSON formatted document containing two key-value pairs with the keys "length" and "width".

To create the test event

1. In the **TEST EVENTS** section of the console code editor, choose **Create test event**.

2. For **Event Name**, enter **myTestEvent**.
3. In the **Event JSON** section, replace the default JSON with the following:

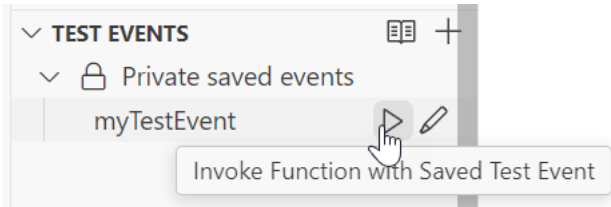

```
{
```

```
"length": 6,  
"width": 7  
}
```

4. Choose **Save**.

To test your function and view invocation records

In the **TEST EVENTS** section of the console code editor, choose the run icon next to your test event:

When your function finishes running, the response and function logs are displayed in the **OUTPUT** tab. You should see results similar to the following:

Node.js

Status: Succeeded

Test Event Name: myTestEvent

Response

```
"{\"area\":42}"
```

When you invoke your function outside of the Lambda console, you must use CloudWatch Logs to view your function's execution results.

To view your function's invocation records in CloudWatch Logs

1. Open the [Log groups](#) page of the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/myLambdaFunction`). This is the log group name that your function printed to the console.
3. Scroll down and choose the **Log stream** for the function invocations you want to look at.

Log streams (14)			Delete	Create log stream	Search all log streams

Clean up

When you're finished working with the example function, delete it. You can also delete the log group that stores the function's logs, and the [execution role](#) that the console created.

To delete the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Select the function that you created.
3. Choose **Actions, Delete**.
4. Type **confirm** in the text input field and choose **Delete**.

To delete the log group

1. Open the [Log groups](#) page of the CloudWatch console.
2. Select the function's log group (`/aws/lambda/myLambdaFunction`).
3. Choose **Actions, Delete log group(s)**.
4. In the **Delete log group(s)** dialog box, choose **Delete**.

To delete the execution role

1. Open the [Roles page](#) of the AWS Identity and Access Management (IAM) console.
2. Select the function's execution role (for example, `myLambdaFunction-role-31exxmpl`).
3. Choose **Delete**.
4. In the **Delete role** dialog box, enter the role name, and then choose **Delete**.

Additional resources and next steps

Now that you've created and tested a simple Lambda function using the console, take these next steps:

- Learn to add dependencies to your function and deploy it using a .zip deployment package. Choose your preferred language from the following links.

Node.js

[the section called "Deploy .zip file archives"](#)

Typescript

[the section called "Deploy .zip file archives"](#)

Python

[the section called "Deploy .zip file archives"](#)

Ruby

[the section called "Deploy .zip file archives"](#)

Java

[the section called "Deploy .zip file archives"](#)

Go

[the section called “Deploy .zip file archives”](#)

C#

[the section called “Deployment package”](#)

- To learn how to invoke a Lambda function using another AWS service, see [Tutorial: Using an Amazon S3 trigger to invoke a Lambda function](#).
- Choose one of the following tutorials for more complex examples of using Lambda with other AWS services.
 - [Tutorial: Using Lambda with API Gateway](#): Create an Amazon API Gateway REST API that invokes a Lambda function.
 - [Using a Lambda function to access an Amazon RDS database](#): Use a Lambda function to write data to an Amazon Relational Database Service (Amazon RDS) database through RDS Proxy.
 - [Using an Amazon S3 trigger to create thumbnail images](#): Use a Lambda function to create a thumbnail every time an image file is uploaded to an Amazon S3 bucket.

Getting started with example applications and patterns

The following resources can be used to quickly create and deploy serverless apps that implement some common Lambda use cases. For each of the example apps, we provide instructions to either create and configure resources manually using the AWS Management Console, or to use the AWS Serverless Application Model to deploy the resources using IaC. Follow the console instructions to learn more about configuring the individual AWS resources for each app, or use the AWS SAM to quickly deploy resources as you would in a production environment.

File Processing

- [PDF Encryption Application](#): Create a serverless application that encrypts PDF files when they are uploaded to an Amazon Simple Storage Service bucket and saves them to another bucket, which is useful for securing sensitive documents upon upload.
- [Image Analysis Application](#): Create a serverless application that extracts text from images using Amazon Rekognition, which is useful for document processing, content moderation, and automated image analysis.

Database Integration

- [Queue-to-Database Application](#): Create a serverless application that writes queue messages to an Amazon RDS database, which is useful for processing user registrations and handling order submissions.
- [Database Event Handler](#): Create a serverless application that responds to Amazon DynamoDB table changes, which is useful for audit logging, data replication, and automated workflows.

Scheduled Tasks

- [Database Maintenance Application](#): Create a serverless application that automatically deletes entries more than 12 months old from an Amazon DynamoDB table using a cron schedule, which is useful for automated database maintenance and data lifecycle management.

- [Create an EventBridge scheduled rule for Lambda functions](#): Use scheduled expressions for rules in EventBridge to trigger a Lambda function on a timed schedule. This format uses cron syntax and can be set with a one-minute granularity.

Long-running Workflows

- [Order Processing Application](#): Create a serverless application using Durable Functions that handles complex order fulfillment, including payment processing, inventory checks, and shipping coordination. This example demonstrates how to build workflows that can run for extended periods while maintaining state.

Additional resources

Use the following resources to further explore Lambda and serverless application development:

- [Serverless Land](#): a library of ready-to-use patterns for building serverless apps. It helps developers create applications faster using AWS services like Lambda, API Gateway, and EventBridge. The site offers pre-built solutions and best practices, making it easier to develop serverless systems.
- [Lambda sample applications](#): Applications that are available in the GitHub repository for this guide. These samples demonstrate the use of various languages and AWS services. Each sample application includes scripts for easy deployment and cleanup and supporting resources.
- [Code examples for Lambda using AWS SDKs](#): Examples that show you how to use Lambda with AWS software development kits (SDKs). These examples include basics, actions, scenarios, and AWS community contributions. Examples cover essential operations, individual service functions, and specific tasks using multiple functions or AWS services.

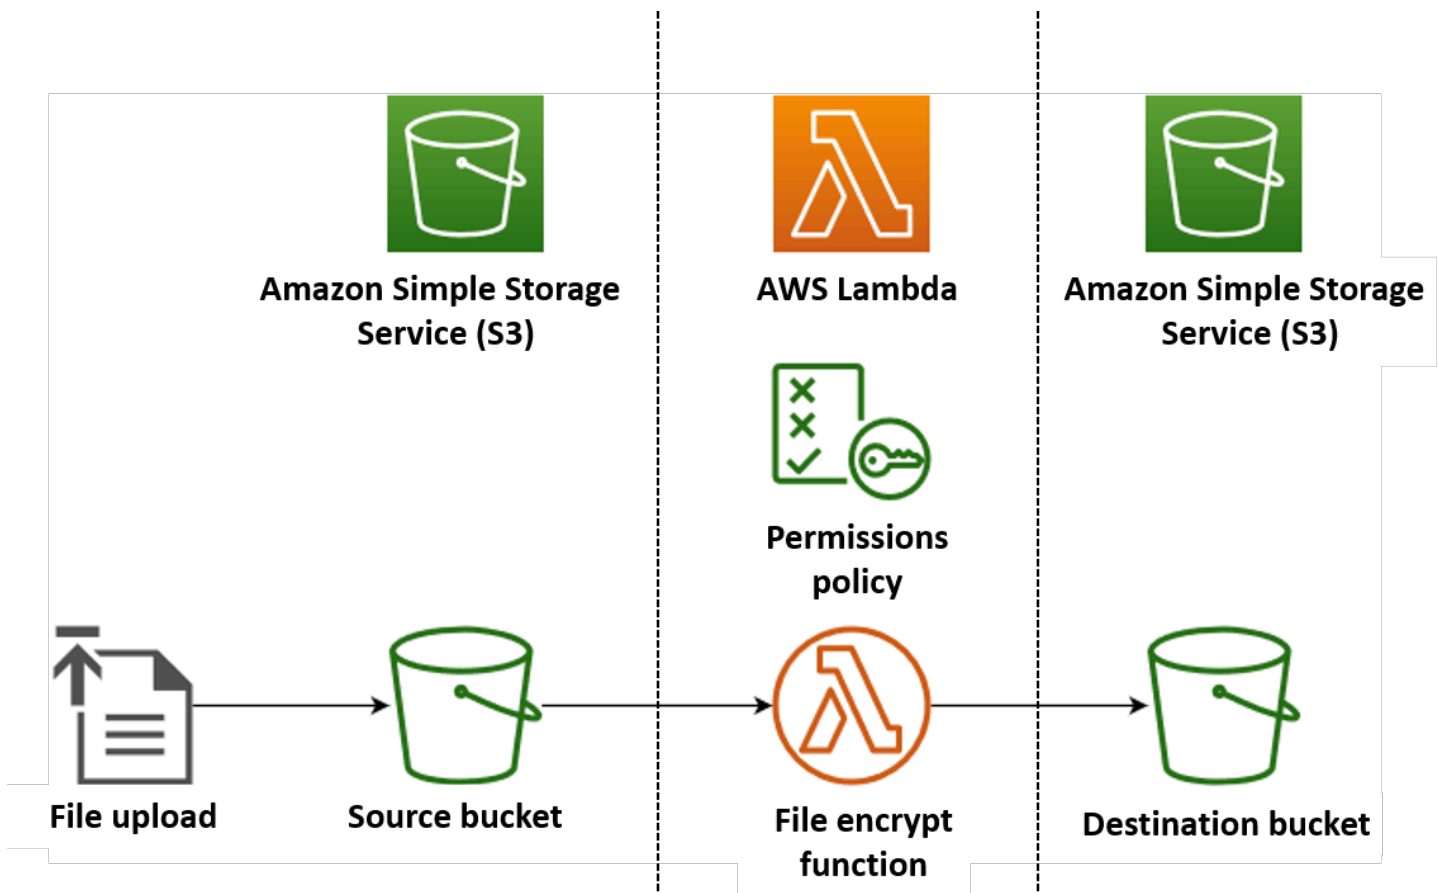

Create a serverless file-processing app

One of the most common use cases for Lambda is to perform file processing tasks. For example, you might use a Lambda function to automatically create PDF files from HTML files or images, or to create thumbnails when a user uploads an image.

In this example, you create an app which automatically encrypts PDF files when they are uploaded to an Amazon Simple Storage Service (Amazon S3) bucket. To implement this app, you create the following resources:

- An S3 bucket for users to upload PDF files to
- A Lambda function in Python which reads the uploaded file and creates an encrypted, password-protected version of it
- A second S3 bucket for Lambda to save the encrypted file in

You also create an AWS Identity and Access Management (IAM) policy to give your Lambda function permission to perform read and write operations on your S3 buckets.

Tip

If you're brand new to Lambda, we recommend that you start with the tutorial [Create your first function](#) before creating this example app.

You can deploy your app manually by creating and configuring resources with the AWS Management Console or the AWS Command Line Interface (AWS CLI). You can also deploy the app by using the AWS Serverless Application Model (AWS SAM). AWS SAM is an infrastructure as code

(IaC) tool. With IaC, you don't create resources manually, but define them in code and then deploy them automatically.

If you want to learn more about using Lambda with IaC before deploying this example app, see [the section called "Infrastructure as code \(IaC\)"](#).

Create the Lambda function source code files

Create the following files in your project directory:

- `lambda_function.py` - the Python function code for the Lambda function that performs the file encryption
- `requirements.txt` - a manifest file defining the dependencies that your Python function code requires

Expand the following sections to view the code and to learn more about the role of each file. To create the files on your local machine, either copy and paste the code below, or download the files from the [aws-lambda-developer-guide GitHub repo](#).

Python function code

Copy and paste the following code into a file named `lambda_function.py`.

```
from pypdf import PdfReader, PdfWriter
import uuid
import os
from urllib.parse import unquote_plus
import boto3

# Create the S3 client to download and upload objects from S3
s3_client = boto3.client('s3')

def lambda_handler(event, context):
    # Iterate over the S3 event object and get the key for all uploaded files
    for record in event['Records']:
        bucket = record['s3']['bucket']['name']
        key = unquote_plus(record['s3']['object']['key']) # Decode the S3 object key to
        # remove any URL-encoded characters
        download_path = f'/tmp/{uuid.uuid4()}.pdf' # Create a path in the Lambda tmp
        # directory to save the file to
```

```
upload_path = f'/tmp/converted-{uuid.uuid4()}.pdf' # Create another path to
save the encrypted file to

# If the file is a PDF, encrypt it and upload it to the destination S3 bucket
if key.lower().endswith('.pdf'):
    s3_client.download_file(bucket, key, download_path)
    encrypt_pdf(download_path, upload_path)
    encrypted_key = add_encrypted_suffix(key)
    s3_client.upload_file(upload_path, f'{bucket}-encrypted', encrypted_key)

# Define the function to encrypt the PDF file with a password
def encrypt_pdf(file_path, encrypted_file_path):
    reader = PdfReader(file_path)
    writer = PdfWriter()

    for page in reader.pages:
        writer.add_page(page)

    # Add a password to the new PDF
    writer.encrypt("my-secret-password")

    # Save the new PDF to a file
    with open(encrypted_file_path, "wb") as file:
        writer.write(file)

# Define a function to add a suffix to the original filename after encryption
def add_encrypted_suffix(original_key):
    filename, extension = original_key.rsplit('.', 1)
    return f'{filename}_encrypted.{extension}'
```

Note

In this example code, a password for the encrypted file (my-secret-password) is hardcoded into the function code. In a production application, don't include sensitive information like passwords in your function code. Instead, [create an AWS Secrets Manager secret](#) and then [use the AWS Parameters and Secrets Lambda extension](#) to retrieve your credentials in your Lambda function.

The python function code contains three functions - the [handler function](#) that Lambda runs when your function is invoked, and two separate function named `add_encrypted_suffix` and `encrypt_pdf` that the handler calls to perform the PDF encryption.

When your function is invoked by Amazon S3, Lambda passes a JSON formatted *event* argument to the function that contains details about the event that caused the invocation. In this case, the information includes name of the S3 bucket and the object keys for the uploaded files. To learn more about the format of event object for Amazon S3, see [the section called "S3"](#).

Your function then uses the AWS SDK for Python (Boto3) to download the PDF files specified in the event object to its local temporary storage directory, before encrypting them using the [pypdf](#) library.

Finally, the function uses the Boto3 SDK to store the encrypted file in your S3 destination bucket.

requirements.txt manifest file

Copy and paste the following code into a file named `requirements.txt`.

```
boto3
pypdf
```

For this example, your function code has only two dependencies that aren't part of the standard Python library - the SDK for Python (Boto3) and the pypdf package the function uses to perform the PDF encryption.

Note

A version of the SDK for Python (Boto3) is included as part of the Lambda runtime, so your code would run without adding Boto3 to your function's deployment package. However, to maintain full control of your function's dependencies and avoid possible issues with version misalignment, best practice for Python is to include all function dependencies in your function's deployment package. See [the section called "Runtime dependencies in Python"](#) to learn more.

Deploy the app

You can create and deploy the resources for this example app either manually or by using AWS SAM. In a production environment, we recommend that you use an IaC tool like AWS SAM to quickly and repeatably deploy whole serverless applications without using manual processes.

Deploy the resources manually

To deploy your app manually:

- Create source and destination Amazon S3 buckets
- Create a Lambda function that encrypts a PDF file and saves the encrypted version to an S3 bucket
- Configure a Lambda trigger that invokes your function when objects are uploaded to your source bucket

Before you begin, make sure that [Python](#) is installed on your build machine.

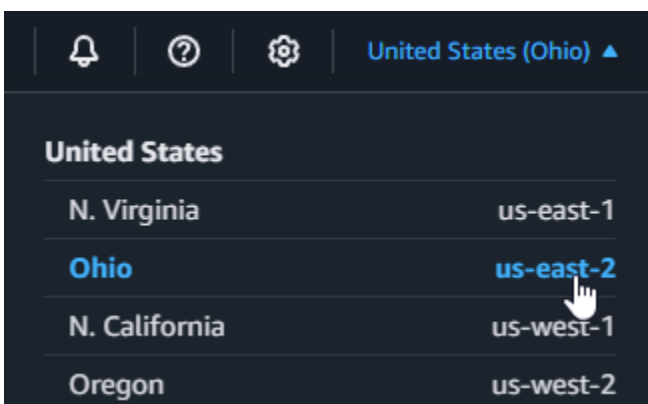

Create two S3 buckets

First create two S3 buckets. The first bucket is the source bucket you will upload your PDF files to. The second bucket is used by Lambda to save the encrypted file when you invoke your function.

Console

To create the S3 buckets (console)

1. Open the [General purpose buckets](#) page of the Amazon S3 console.
2. Select the AWS Region closest to your geographical location. You can change your region using the drop-down list at the top of the screen.

3. Choose **Create bucket**.
4. Under **General configuration**, do the following:
 - a. For **Bucket type**, ensure **General purpose** is selected.
 - b. For **Bucket name**, enter a globally unique name that meets the Amazon S3 [bucket naming rules](#). Bucket names can contain only lower case letters, numbers, dots (.), and hyphens (-).
5. Leave all other options set to their default values and choose **Create bucket**.
6. Repeat steps 1 to 4 to create your destination bucket. For **Bucket name**, enter **amzn-s3-demo-bucket-encrypted**, where **amzn-s3-demo-bucket** is the name of the source bucket you just created.

AWS CLI

Before you begin, make sure that the [AWS CLI is installed](#) on your build machine.

To create the Amazon S3 buckets (AWS CLI)

1. Run the following CLI command to create your source bucket. The name you choose for your bucket must be globally unique and follow the Amazon S3 [bucket naming rules](#). Names can only contain lower case letters, numbers, dots (.), and hyphens (-). For region and LocationConstraint, choose the [AWS Region](#) closest to your geographical location.

```
aws s3api create-bucket --bucket amzn-s3-demo-bucket --region us-east-2 \
--create-bucket-configuration LocationConstraint=us-east-2
```

Later in the tutorial, you must create your Lambda function in the same AWS Region as your source bucket, so make a note of the region you chose.

2. Run the following command to create your destination bucket. For the bucket name, you must use **amzn-s3-demo-bucket-encrypted**, where **amzn-s3-demo-bucket** is the name of the source bucket you created in step 1. For region and LocationConstraint, choose the same AWS Region you used to create your source bucket.

```
aws s3api create-bucket --bucket amzn-s3-demo-bucket-encrypted --region us-east-2 \
--create-bucket-configuration LocationConstraint=us-east-2
```

Create an execution role

An execution role is an IAM role that grants a Lambda function permission to access AWS services and resources. To give your function read and write access to Amazon S3, you attach the [AWS managed policy](#) `AmazonS3FullAccess`.

Console

To create an execution role and attach the `AmazonS3FullAccess` managed policy (console)

1. Open the [Roles](#) page in the IAM console.
2. Choose **Create role**.
3. For **Trusted entity type**, select **AWS service**, and for **Use case**, select **Lambda**.
4. Choose **Next**.
5. Add the `AmazonS3FullAccess` managed policy by doing the following:
 - a. In **Permissions policies**, enter **`AmazonS3FullAccess`** into the search bar.
 - b. Select the checkbox next to the policy.
 - c. Choose **Next**.
6. In **Role details**, for **Role name** enter **`LambdaS3Role`**.
7. Choose **Create Role**.

AWS CLI

To create an execution role and attach the `AmazonS3FullAccess` managed policy (AWS CLI)

1. Save the following JSON in a file named `trust-policy.json`. This trust policy allows Lambda to use the role's permissions by giving the service principal `lambda.amazonaws.com` permission to call the AWS Security Token Service (AWS STS) `AssumeRole` action.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
```

```
    "Service": "lambda.amazonaws.com"
  },
  "Action": "sts:AssumeRole"
}
]
```

2. From the directory you saved the JSON trust policy document in, run the following CLI command to create the execution role.

```
aws iam create-role --role-name LambdaS3Role --assume-role-policy-document
file://trust-policy.json
```

3. To attach the AmazonS3FullAccess managed policy, run the following CLI command.

```
aws iam attach-role-policy --role-name LambdaS3Role --policy-arn
arn:aws:iam::aws:policy/AmazonS3FullAccess
```

Create the function deployment package

To create your function, you create a *deployment package* containing your function code and its dependencies. For this application, your function code uses a separate library for the PDF encryption.

To create the deployment package

1. Navigate to the project directory containing the `lambda_function.py` and `requirements.txt` files you created or downloaded from GitHub earlier and create a new directory named `package`.
2. Install the dependencies specified in the `requirements.txt` file in your package directory by running the following command.

```
pip install -r requirements.txt --target ./package/
```

3. Create a `.zip` file containing your application code and its dependencies. In Linux or MacOS, run the following commands from your command line interface.

```
cd package
zip -r ../lambda_function.zip .
cd ..
```

```
zip lambda_function.zip lambda_function.py
```

In Windows, use your preferred zip tool to create the `lambda_function.zip` file. Make sure that your `lambda_function.py` file and the folders containing your dependencies are all at the root of the .zip file.

You can also create your deployment package using a Python virtual environment. See [Working with .zip file archives for Python Lambda functions](#)

Create the Lambda function

You now use the deployment package you created in the previous step to deploy your Lambda function.

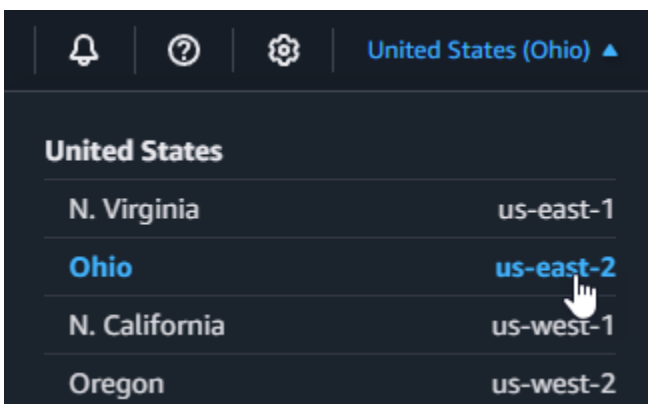

Console

To create the function (console)

To create your Lambda function using the console, you first create a basic function containing some 'Hello world' code. You then replace this code with your own function code by uploading the.zip file you created in the previous step.

To ensure that your function doesn't time out when encrypting large PDF files, you configure the function's memory and timeout settings. You also set the function's log format to JSON. Configuring JSON formatted logs is necessary when using the provided test script so it can read the function's invocation status from CloudWatch Logs to confirm successful invocation.

1. Open the [Functions page](#) of the Lambda console.
2. Make sure you're working in the same AWS Region you created your S3 bucket in. You can change your region using the drop-down list at the top of the screen.

3. Choose **Create function**.
4. Choose **Author from scratch**.
5. Under **Basic information**, do the following:
 - a. For **Function name**, enter **EncryptPDF**.
 - b. For **Runtime** choose **Python 3.12**.
 - c. For **Architecture**, choose **x86_64**.
6. Attach the execution role you created in the previous step by doing the following:
 - a. Expand the **Change default execution role** section.
 - b. Select **Use an existing role**.
 - c. Under **Existing role**, select your role (LambdaS3Role).
7. Choose **Create function**.

To upload the function code (console)

1. In the **Code source** pane, choose **Upload from**.
2. Choose **.zip file**.
3. Choose **Upload**.
4. In the file selector, select your .zip file and choose **Open**.
5. Choose **Save**.

To configure the function memory and timeout (console)

1. Select the **Configuration** tab for your function.
2. In the **General configuration** pane, choose **Edit**.
3. Set **Memory** to 256 MB and **Timeout** to 15 seconds.
4. Choose **Save**.

To configure the log format (console)

1. Select the **Configuration** tab for your function.
2. Select **Monitoring and operations tools**.
3. In the **Logging configuration** pane, choose **Edit**.

4. For **Logging configuration**, select **JSON**.
5. Choose **Save**.

AWS CLI

To create the function (AWS CLI)

- Run the following command from the directory containing your `lambda_function.zip` file. For the `region` parameter, replace `us-east-2` with the region you created your S3 buckets in.

```
aws lambda create-function --function-name EncryptPDF \
--zip-file fileb://lambda_function.zip --handler lambda_function.lambda_handler \
--runtime python3.12 --timeout 15 --memory-size 256 \
--role arn:aws:iam::123456789012:role/LambdaS3Role --region us-east-2 \
--logging-config LogFormat=JSON
```

Configure an Amazon S3 trigger to invoke the function

For your Lambda function to run when you upload a file to your source bucket, you need to configure a trigger for your function. You can configure the Amazon S3 trigger using either the console or the AWS CLI.

Important

This procedure configures the S3 bucket to invoke your function every time that an object is created in the bucket. Be sure to configure this only on the source bucket. If your Lambda function creates objects in the same bucket that invokes it, your function can be [invoked continuously in a loop](#). This can result in unexpected charges being billed to your AWS account.

Console

To configure the Amazon S3 trigger (console)

1. Open the [Functions page](#) of the Lambda console and choose your function (EncryptPDF).

2. Choose **Add trigger**.
3. Select **S3**.
4. Under **Bucket**, select your source bucket.
5. Under **Event types**, select **All object create events**.
6. Under **Recursive invocation**, select the check box to acknowledge that using the same S3 bucket for input and output is not recommended. You can learn more about recursive invocation patterns in Lambda by reading [Recursive patterns that cause run-away Lambda functions](#) in Serverless Land.
7. Choose **Add**.

When you create a trigger using the Lambda console, Lambda automatically creates a [resource based policy](#) to give the service you select permission to invoke your function.

AWS CLI

To configure the Amazon S3 trigger (AWS CLI)

1. Add a [resource based policy](#) to your function that allows your Amazon S3 source bucket to invoke your function when you add a file. A resource-based policy statement gives other AWS services permission to invoke your function. To give Amazon S3 permission to invoke your function, run the following CLI command. Be sure to replace the source-account parameter with your own AWS account ID and to use your own source bucket name.

```
aws lambda add-permission --function-name EncryptPDF \  
--principal s3.amazonaws.com --statement-id s3invoke --action \  
"lambda:InvokeFunction" \  
--source-arn arn:aws:s3:::amzn-s3-demo-bucket \  
--source-account 123456789012
```

The policy you define with this command allows Amazon S3 to invoke your function only when an action takes place on your source bucket.

Note

Although S3 bucket names are globally unique, when using resource-based policies it is best practice to specify that the bucket must belong to your account. This is

because if you delete a bucket, it is possible for another AWS account to create a bucket with the same Amazon Resource Name (ARN).

2. Save the following JSON in a file named `notification.json`. When applied to your source bucket, this JSON configures the bucket to send a notification to your Lambda function every time a new object is added. Replace the AWS account number and AWS Region in the Lambda function ARN with your own account number and region.

```
{
  "LambdaFunctionConfigurations": [
    {
      "Id": "EncryptPDFAEventConfiguration",
      "LambdaFunctionArn": "arn:aws:lambda:us-
east-2:123456789012:function:EncryptPDF",
      "Events": [ "s3:ObjectCreated:Put" ]
    }
  ]
}
```

3. Run the following CLI command to apply the notification settings in the JSON file you created to your source bucket. Replace `amzn-s3-demo-bucket` with the name of your own source bucket.

```
aws s3api put-bucket-notification-configuration --bucket amzn-s3-demo-bucket \
--notification-configuration file://notification.json
```

To learn more about the `put-bucket-notification-configuration` command and the `notification-configuration` option, see [put-bucket-notification-configuration](#) in the *AWS CLI Command Reference*.

Deploy the resources using AWS SAM

Before you begin, make sure that [Docker](#) and [the latest version of the AWS SAM CLI](#) are installed on your build machine.

1. In your project directory, copy and paste the following code into a file named `template.yaml`. Replace the placeholder bucket names:

- For the source bucket, replace `amzn-s3-demo-bucket` with any name that complies with the [S3 bucket naming rules](#).
- For the destination bucket, replace `amzn-s3-demo-bucket-encrypted` with `<source-bucket-name>-encrypted`, where `<source-bucket>` is the name you chose for your source bucket.

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31

Resources:
  EncryptPDFFunction:
    Type: AWS::Serverless::Function
    Properties:
      FunctionName: EncryptPDF
      Architectures: [x86_64]
      CodeUri: ./
      Handler: lambda_function.lambda_handler
      Runtime: python3.12
      Timeout: 15
      MemorySize: 256
      LoggingConfig:
        LogFormat: JSON
      Policies:
        - AmazonS3FullAccess
      Events:
        S3Event:
          Type: S3
          Properties:
            Bucket: !Ref PDFSourceBucket
            Events: s3:ObjectCreated:*

  PDFSourceBucket:
    Type: AWS::S3::Bucket
    Properties:
      BucketName: amzn-s3-demo-bucket

  EncryptedPDFBucket:
    Type: AWS::S3::Bucket
    Properties:
      BucketName: amzn-s3-demo-bucket-encrypted
```

The AWS SAM template defines the resources you create for your app. In this example, the template defines a Lambda function using the `AWS::Serverless::Function` type and two S3 buckets using the `AWS::S3::Bucket` type. The bucket names specified in the template are placeholders. Before you deploy the app using AWS SAM, you need to edit the template to rename the buckets with globally unique names that meet the [S3 bucket naming rules](#). This step is explained further in [the section called “Deploy the resources using AWS SAM”](#).

The definition of the Lambda function resource configures a trigger for the function using the `S3Event` event property. This trigger causes your function to be invoked whenever an object is created in your source bucket.

The function definition also specifies an AWS Identity and Access Management (IAM) policy to be attached to the function's [execution role](#). The [AWS managed policy](#) `AmazonS3FullAccess` gives your function the permissions it needs to read and write objects to Amazon S3.

2. Run the following command from the directory in which you saved your `template.yaml`, `lambda_function.py`, and `requirements.txt` files.

```
sam build --use-container
```

This command gathers the build artifacts for your application and places them in the proper format and location to deploy them. Specifying the `--use-container` option builds your function inside a Lambda-like Docker container. We use it here so you don't need to have Python 3.12 installed on your local machine for the build to work.

During the build process, AWS SAM looks for the Lambda function code in the location you specified with the `CodeUri` property in the template. In this case, we specified the current directory as the location (`./`).

If a `requirements.txt` file is present, AWS SAM uses it to gather the specified dependencies. By default, AWS SAM creates a .zip deployment package with your function code and dependencies. You can also choose to deploy your function as a container image using the [PackageType](#) property.

3. To deploy your application and create the Lambda and Amazon S3 resources specified in your AWS SAM template, run the following command.

```
sam deploy --guided
```

Using the `--guided` flag means that AWS SAM will show you prompts to guide you through the deployment process. For this deployment, accept the default options by pressing Enter.

During the deployment process, AWS SAM creates the following resources in your AWS account:

- An CloudFormation [stack](#) named `sam-app`
- A Lambda function with the name `EncryptPDF`
- Two S3 buckets with the names you chose when you edited the `template.yaml` AWS SAM template file
- An IAM execution role for your function with the name `format sam-app-EncryptPDFFunctionRole-2qGaapHFW0Q8`

When AWS SAM finishes creating your resources, you should see the following message:

```
Successfully created/updated stack - sam-app in us-east-2
```

Test the app

To test your app, upload a PDF file to your source bucket, and confirm that Lambda creates an encrypted version of the file in your destination bucket. In this example, you can either test this manually using the console or the AWS CLI, or by using the provided test script.

For production applications, you can use traditional test methods and techniques, such as unit testing, to confirm the correct functioning of your Lambda function code. Best practice is also to conduct tests like those in the provided test script which perform integration testing with real, cloud-based resources. Integration testing in the cloud confirms that your infrastructure has been correctly deployed and that events flow between different services as expected. To learn more, see [Testing serverless functions](#).

Testing the app manually

You can test your function manually by adding a PDF file to your Amazon S3 source bucket. When you add your file to the source bucket, your Lambda function should be automatically invoked and should store an encrypted version of the file in your target bucket.

Console

To test your app by uploading a file (console)

1. To upload a PDF file to your S3 bucket, do the following:
 - a. Open the [Buckets](#) page of the Amazon S3 console and choose your source bucket.
 - b. Choose **Upload**.
 - c. Choose **Add files** and use the file selector to choose the PDF file you want to upload.
 - d. Choose **Open**, then choose **Upload**.
2. Verify that Lambda has saved an encrypted version of your PDF file in your target bucket by doing the following:
 - a. Navigate back to the [Buckets](#) page of the Amazon S3 console and choose your destination bucket.
 - b. In the **Objects** pane, you should now see a file with name format `filename_encrypted.pdf` (where `filename.pdf` was the name of the file you uploaded to your source bucket). To download your encrypted PDF, select the file, then choose **Download**.
 - c. Confirm that you can open the downloaded file with the password your Lambda function protected it with (`my-secret-password`).

AWS CLI

To test your app by uploading a file (AWS CLI)

1. From the directory containing the PDF file you want to upload, run the following CLI command. Replace the `--bucket` parameter with the name of your source bucket. For the `--key` and `--body` parameters, use the filename of your test file.

```
aws s3api put-object --bucket amzn-s3-demo-bucket --key test.pdf --body ./  
test.pdf
```

2. Verify that your function has created an encrypted version of your file and saved it to your target S3 bucket. Run the following CLI command, replacing `amzn-s3-demo-bucket-encrypted` with the name of your own destination bucket.

```
aws s3api list-objects-v2 --bucket amzn-s3-demo-bucket-encrypted
```

If your function runs successfully, you'll see output similar to the following. Your target bucket should contain a file with the name format **<your_test_file>_encrypted.pdf**, where **<your_test_file>** is the name of the file you uploaded.

```
{
  "Contents": [
    {
      "Key": "test_encrypted.pdf",
      "LastModified": "2023-06-07T00:15:50+00:00",
      "ETag": "\"7781a43e765a8301713f533d70968a1e\"",
      "Size": 2763,
      "StorageClass": "STANDARD"
    }
  ]
}
```

3. To download the file that Lambda saved in your destination bucket, run the following CLI command. Replace the `--bucket` parameter with the name of your destination bucket. For the `--key` parameter, use the filename **<your_test_file>_encrypted.pdf**, where **<your_test_file>** is the name of the the test file you uploaded.

```
aws s3api get-object --bucket amzn-s3-demo-bucket-encrypted --  
key test_encrypted.pdf my_encrypted_file.pdf
```

This command downloads the file to your current directory and saves it as `my_encrypted_file.pdf`.

4. Confirm the you can open the downloaded file with the password your Lambda function protected it with (`my-secret-password`).

Testing the app with the automated script

Create the following files in your project directory:

- `test_pdf_encrypt.py` - a test script you can use to automatically test your application
- `pytest.ini` - a configuration file for the the test script

Expand the following sections to view the code and to learn more about the role of each file.

Automated test script

Copy and paste the following code into a file named `test_pdf_encrypt.py`. Be sure to replace the placeholder bucket names:

- In the `test_source_bucket_available` function, replace `amzn-s3-demo-bucket` with the name of your source bucket.
- In the `test_encrypted_file_in_bucket` function, replace `amzn-s3-demo-bucket-encrypted` with `source-bucket-encrypted`, where `source-bucket` is the name of your source bucket.
- In the `cleanup` function, replace `amzn-s3-demo-bucket` with the name of your source bucket, and replace `amzn-s3-demo-bucket-encrypted` with the name of your destination bucket.

```
import boto3
import json
import pytest
import time
import os

@pytest.fixture
def lambda_client():
    return boto3.client('lambda')

@pytest.fixture
def s3_client():
    return boto3.client('s3')

@pytest.fixture
def logs_client():
    return boto3.client('logs')

@pytest.fixture(scope='session')
def cleanup():
    # Create a new S3 client for cleanup
    s3_client = boto3.client('s3')

    yield

    # Cleanup code will be executed after all tests have finished
```

```

# Delete test.pdf from the source bucket
source_bucket = 'amzn-s3-demo-bucket'
source_file_key = 'test.pdf'
s3_client.delete_object(Bucket=source_bucket, Key=source_file_key)
print(f"\nDeleted {source_file_key} from {source_bucket}")

# Delete test_encrypted.pdf from the destination bucket
destination_bucket = 'amzn-s3-demo-bucket-encrypted'
destination_file_key = 'test_encrypted.pdf'
s3_client.delete_object(Bucket=destination_bucket, Key=destination_file_key)
print(f"Deleted {destination_file_key} from {destination_bucket}")

@pytest.mark.order(1)
def test_source_bucket_available(s3_client):
    s3_bucket_name = 'amzn-s3-demo-bucket'
    file_name = 'test.pdf'
    file_path = os.path.join(os.path.dirname(__file__), file_name)

    file_uploaded = False
    try:
        s3_client.upload_file(file_path, s3_bucket_name, file_name)
        file_uploaded = True
    except:
        print("Error: couldn't upload file")

    assert file_uploaded, "Could not upload file to S3 bucket"

@pytest.mark.order(2)
def test_lambda_invoked(logs_client):

    # Wait for a few seconds to make sure the logs are available
    time.sleep(5)

    # Get the latest log stream for the specified log group
    log_streams = logs_client.describe_log_streams(
        logGroupName='/aws/lambda/EncryptPDF',
        orderBy='LastEventTime',
        descending=True,
        limit=1
    )

```

```

latest_log_stream_name = log_streams['logStreams'][0]['logStreamName']

# Retrieve the log events from the latest log stream
log_events = logs_client.get_log_events(
    logGroupName='/aws/lambda/EncryptPDF',
    logStreamName=latest_log_stream_name
)

success_found = False
for event in log_events['events']:
    message = json.loads(event['message'])
    status = message.get('record', {}).get('status')
    if status == 'success':
        success_found = True
        break

assert success_found, "Lambda function execution did not report 'success' status in logs."

@pytest.mark.order(3)
def test_encrypted_file_in_bucket(s3_client):
    # Specify the destination S3 bucket and the expected converted file key
    destination_bucket = 'amzn-s3-demo-bucket-encrypted'
    converted_file_key = 'test_encrypted.pdf'

    try:
        # Attempt to retrieve the metadata of the converted file from the destination
        # S3 bucket
        s3_client.head_object(Bucket=destination_bucket, Key=converted_file_key)
    except s3_client.exceptions.ClientError as e:
        # If the file is not found, the test will fail
        pytest.fail(f"Converted file '{converted_file_key}' not found in the
        destination bucket: {str(e)}")

def test_cleanup(cleanup):
    # This test uses the cleanup fixture and will be executed last
    pass

```

The automated test script executes three test functions to confirm correct operation of your app:

- The test `test_source_bucket_available` confirms that your source bucket has been successfully created by uploading a test PDF file to the bucket.

- The test `test_lambda_invoked` interrogates the latest CloudWatch Logs log stream for your function to confirm that when you uploaded the test file, your Lambda function ran and reported success.
- The test `test_encrypted_file_in_bucket` confirms that your destination bucket contains the encrypted `test_encrypted.pdf` file.

After all these tests have run, the script runs an additional cleanup step to delete the `test.pdf` and `test_encrypted.pdf` files from both your source and destination buckets.

As with the AWS SAM template, the bucket names specified in this file are placeholders. Before running the test, you need to edit this file with your app's real bucket names. This step is explained further in [the section called “Testing the app with the automated script”](#)

Test script configuration file

Copy and paste the following code into a file named `pytest.ini`.

```
[pytest]
markers =
    order: specify test execution order
```

This is needed to specify the order in which the tests in the `test_pdf_encrypt.py` script run.

To run the tests do the following:

1. Ensure that the `pytest` module is installed in your local environment. You can install `pytest` by running the following command:

```
pip install pytest
```

2. Save a PDF file named `test.pdf` in the directory containing the `test_pdf_encrypt.py` and `pytest.ini` files.
3. Open a terminal or shell program and run the following command from the directory containing the test files.

```
pytest -s -v
```

When the test completes, you should see output like the following:

```

===== test session starts
=====
platform linux -- Python 3.12.2, pytest-7.2.2, pluggy-1.0.0 -- /usr/bin/python3
cachedir: .pytest_cache
hypothesis profile 'default' -> database=DirectoryBasedExampleDatabase('/home/
pdf_encrypt_app/.hypothesis/examples')
Test order randomisation NOT enabled. Enable with --random-order or --random-order-
bucket=<bucket_type>

```

Next steps

Now you've created this example app, you can use the provided code as a basis to create other types of file-processing application. Modify the code in the `lambda_function.py` file to implement the file-processing logic for your use case.

Many typical file-processing use cases involve image processing. When using Python, the most popular image-processing libraries like [pillow](#) typically contain C or C++ components. In order to ensure that your function's deployment package is compatible with the Lambda execution environment, it's important to use the correct source distribution binary.

When deploying your resources with AWS SAM, you need to take some extra steps to include the right source distribution in your deployment package. Because AWS SAM won't install dependencies for a different platform than your build machine, specifying the correct source distribution (.whl file) in your `requirements.txt` file won't work if your build machine uses an

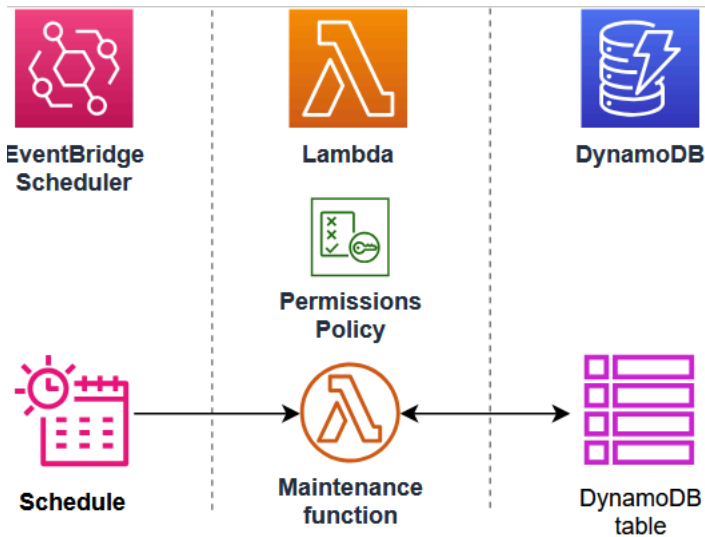

operating system or architecture that's different from the Lambda execution environment. Instead, you should do one of the following:

- Use the `--use-container` option when running `sam build`. When you specify this option, AWS SAM downloads a container base image that's compatible with the Lambda execution environment and builds your function's deployment package in a Docker container using that image. To learn more, see [Building a Lambda function inside of a provided container](#).
- Build your function's .zip deployment package yourself using the correct source distribution binary and save the .zip file in the directory you specify as the `CodeUri` in the AWS SAM template. To learn more about building .zip deployment packages for Python using binary distributions, see [the section called "Creating a .zip deployment package with dependencies"](#) and [the section called "Creating .zip deployment packages with native libraries"](#).

Create an app to perform scheduled database maintenance

You can use AWS Lambda to replace scheduled processes such as automated system backups, file conversions, and maintenance tasks. In this example, you create a serverless application that performs regular scheduled maintenance on a DynamoDB table by deleting old entries. The app uses EventBridge Scheduler to invoke a Lambda function on a cron schedule. When invoked, the function queries the table for items older than one year, and deletes them. The function logs each deleted item in CloudWatch Logs.

To implement this example, first create a DynamoDB table and populate it with some test data for your function to query. Then, create a Python Lambda function with an EventBridge Scheduler trigger and an IAM execution role that gives the function permission to read, and delete, items from your table.

**Tip**

If you're new to Lambda, we recommend that you complete the tutorial [Create your first function](#) before creating this example app.

You can deploy your app manually by creating and configuring resources with the AWS Management Console. You can also deploy the app by using the AWS Serverless Application Model (AWS SAM). AWS SAM is an infrastructure as code (IaC) tool. With IaC, you don't create resources manually, but define them in code and then deploy them automatically.

If you want to learn more about using Lambda with IaC before deploying this example app, see [the section called "Infrastructure as code \(IaC\)"](#).

Prerequisites

Before you can create the example app, make sure you have the required command line tools and programs installed.

- **Python**

To populate the DynamoDB table you create to test your app, this example uses a Python script and a CSV file to write data into the table. Make sure you have Python version 3.8 or later installed on your machine.

- **AWS SAM CLI**

If you want to create the DynamoDB table and deploy the example app using AWS SAM, you need to install the AWS SAM CLI. Follow the [installation instructions](#) in the *AWS SAM User Guide*.

- **AWS CLI**

To use the provided Python script to populate your test table, you need to have installed and configured the AWS CLI. This is because the script uses the AWS SDK for Python (Boto3), which needs access to your AWS Identity and Access Management (IAM) credentials. You also need the AWS CLI installed to deploy resources using AWS SAM. Install the CLI by following the [installation instructions](#) in the *AWS Command Line Interface User Guide*.

- **Docker**

To deploy the app using AWS SAM, Docker must also be installed on your build machine. Follow the instructions in [Install Docker Engine](#) on the Docker documentation website.

Downloading the example app files

To create the example database and the scheduled-maintenance app, you need to create the following files in your project directory:

Example database files

- `template.yaml` - an AWS SAM template you can use to create the DynamoDB table
- `sample_data.csv` - a CSV file containing sample data to load into your table
- `load_sample_data.py` - a Python script that writes the data in the CSV file into the table

Scheduled-maintenance app files

- `lambda_function.py` - the Python function code for the Lambda function that performs the database maintenance
- `requirements.txt` - a manifest file defining the dependencies that your Python function code requires
- `template.yaml` - an AWS SAM template you can use to deploy the app

Test file

- `test_app.py` - a Python script that scans the table and confirms successful operation of your function by outputting all records older than one year

Expand the following sections to view the code and to learn more about the role of each file in creating and testing your app. To create the files on your local machine, copy and paste the code below.

AWS SAM template (example DynamoDB table)

Copy and paste the following code into a file named `template.yaml`.

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: SAM Template for DynamoDB Table with Order_number as Partition Key and
  Date as Sort Key

Resources:
  MyDynamoDBTable:
    Type: AWS::DynamoDB::Table
    DeletionPolicy: Retain
    UpdateReplacePolicy: Retain
    Properties:
      TableName: MyOrderTable
      BillingMode: PAY_PER_REQUEST
      AttributeDefinitions:
        - AttributeName: Order_number
          AttributeType: S
        - AttributeName: Date
          AttributeType: S
      KeySchema:
        - AttributeName: Order_number
          KeyType: HASH
        - AttributeName: Date
          KeyType: RANGE
      SSESpecification:
        SSEEnabled: true
      GlobalSecondaryIndexes:
        - IndexName: Date-index
          KeySchema:
            - AttributeName: Date
              KeyType: HASH
          Projection:
```

```

    ProjectionType: ALL
    PointInTimeRecoverySpecification:
      PointInTimeRecoveryEnabled: true

```

Outputs:

```

TableName:
  Description: DynamoDB Table Name
  Value: !Ref MyDynamoDBTable
TableArn:
  Description: DynamoDB Table ARN
  Value: !GetAtt MyDynamoDBTable.Arn

```

Note

AWS SAM templates use a standard naming convention of `template.yaml`. In this example, you have two template files - one to create the example database and another to create the app itself. Save them in separate sub-directories in your project folder.

This AWS SAM template defines the DynamoDB table resource you create to test your app. The table uses a primary key of `Order_number` with a sort key of `Date`. In order for your Lambda function to find items directly by date, we also define a [Global Secondary Index](#) named `Date-index`.

To learn more about creating and configuring a DynamoDB table using the `AWS::DynamoDB::Table` resource, see [AWS::DynamoDB::Table](#) in the *AWS CloudFormation User Guide*.

Sample database data file

Copy and paste the following code into a file named `sample_data.csv`.

```

Date,Order_number,CustomerName,ProductID,Quantity,TotalAmount
2023-09-01,ORD001,Alejandro Rosalez,PROD123,2,199.98

```

This file contains some example test data to populate your DynamoDB table with in a standard comma-separated values (CSV) format.

Python script to load sample data

Copy and paste the following code into a file named `load_sample_data.py`.

```

import boto3
import csv
from decimal import Decimal

# Initialize the DynamoDB client
dynamodb = boto3.resource('dynamodb')
table = dynamodb.Table('MyOrderTable')
print("DDB client initialized.")

def load_data_from_csv(filename):
    with open(filename, 'r') as file:
        csv_reader = csv.DictReader(file)
        for row in csv_reader:
            item = {
                'Order_number': row['Order_number'],
                'Date': row['Date'],
                'CustomerName': row['CustomerName'],
                'ProductID': row['ProductID'],
                'Quantity': int(row['Quantity']),
            }

```

```

        'TotalAmount': Decimal(str(row['TotalAmount']))
    }
    table.put_item(Item=item)
    print(f"Added item: {item['Order_number']} - {item['Date']}")

if __name__ == "__main__":
    load_data_from_csv('sample_data.csv')
    print("Data loading completed.")

```

This Python script first uses the AWS SDK for Python (Boto3) to create a connection to your DynamoDB table. It then iterates over each row in the example-data CSV file, creates an item from that row, and writes the item to the DynamoDB table using the boto3 SDK.

Python function code

Copy and paste the following code into a file named `lambda_function.py`.

```

import boto3
from datetime import datetime, timedelta
from boto3.dynamodb.conditions import Key, Attr
import logging

logger = logging.getLogger()
logger.setLevel("INFO")

def lambda_handler(event, context):
    # Initialize the DynamoDB client
    dynamodb = boto3.resource('dynamodb')

    # Specify the table name
    table_name = 'MyOrderTable'
    table = dynamodb.Table(table_name)

    # Get today's date
    today = datetime.now()

    # Calculate the date one year ago
    one_year_ago = (today - timedelta(days=365)).strftime('%Y-%m-%d')

    # Scan the table using a global secondary index
    response = table.scan(
        IndexName='Date-index',
        FilterExpression='#date < :one_year_ago',

```

```

        ExpressionAttributeNames={
            '#date': 'Date'
        },
        ExpressionAttributeValues={
            ':one_year_ago': one_year_ago
        }
    )

    # Delete old items
    with table.batch_writer() as batch:
        for item in response['Items']:
            Order_number = item['Order_number']
            batch.delete_item(
                Key={
                    'Order_number': Order_number,
                    'Date': item['Date']
                }
            )
            logger.info(f'deleted order number {Order_number}')

# Check if there are more items to scan
while 'LastEvaluatedKey' in response:
    response = table.scan(
        IndexName='DateIndex',
        FilterExpression='#date < :one_year_ago',
        ExpressionAttributeNames={
            '#date': 'Date'
        },
        ExpressionAttributeValues={
            ':one_year_ago': one_year_ago
        },
        ExclusiveStartKey=response['LastEvaluatedKey']
    )

    # Delete old items
    with table.batch_writer() as batch:
        for item in response['Items']:
            batch.delete_item(
                Key={
                    'Order_number': item['Order_number'],
                    'Date': item['Date']
                }
            )

```

```
return {  
    'statusCode': 200,  
    'body': 'Cleanup completed successfully'  
}
```

The Python function code contains the [handler function](#) (`lambda_handler`) that Lambda runs when your function is invoked.

When the function is invoked by EventBridge Scheduler, it uses the AWS SDK for Python (Boto3) to create a connection to the DynamoDB table on which the scheduled maintenance task is to be performed. It then uses the Python `datetime` library to calculate the date one year ago, before scanning the table for items older than this and deleting them.

Note that responses from DynamoDB query and scan operations are limited to a maximum of 1 MB in size. If the response is larger than 1 MB, DynamoDB paginates the data and returns a `LastEvaluatedKey` element in the response. To ensure that our function processes all the records in the table, we check for the presence of this key and continue performing table scans from the last evaluated position until the whole table has been scanned.

requirements.txt manifest file

Copy and paste the following code into a file named `requirements.txt`.

```
boto3
```

For this example, your function code has only one dependency that isn't part of the standard Python library - the SDK for Python (Boto3) that the function uses to scan and delete items from the DynamoDB table.

Note

A version of the SDK for Python (Boto3) is included as part of the Lambda runtime, so your code would run without adding Boto3 to your function's deployment package. However, to maintain full control of your function's dependencies and avoid possible issues with version misalignment, best practice for Python is to include all function dependencies in your function's deployment package. See [the section called “Runtime dependencies in Python”](#) to learn more.

AWS SAM template (scheduled-maintenance app)

Copy and paste the following code into a file named `template.yaml`.

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: SAM Template for Lambda function and EventBridge Scheduler rule

Resources:
  MyLambdaFunction:
    Type: AWS::Serverless::Function
    Properties:
      FunctionName: ScheduledDBMaintenance
      CodeUri: ./
      Handler: lambda_function.lambda_handler
      Runtime: python3.11
      Architectures:
        - x86_64
      Events:
        ScheduleEvent:
          Type: ScheduleV2
          Properties:
            ScheduleExpression: cron(0 3 1 * ? *)
            Description: Run on the first day of every month at 03:00 AM
      Policies:
        - CloudWatchLogsFullAccess
        - Statement:
            - Effect: Allow
              Action:
                - dynamodb:Scan
                - dynamodb:BatchWriteItem
              Resource: !Sub 'arn:aws:dynamodb:${AWS::Region}:${AWS::AccountId}:table/MyOrderTable'

  LambdaLogGroup:
    Type: AWS::Logs::LogGroup
    Properties:
      LogGroupName: !Sub /aws/lambda/${MyLambdaFunction}
      RetentionInDays: 30

Outputs:
  LambdaFunctionName:
    Description: Lambda Function Name
    Value: !Ref MyLambdaFunction
```

```
LambdaFunctionArn:  
  Description: Lambda Function ARN  
  Value: !GetAtt MyLambdaFunction.Arn
```

Note

AWS SAM templates use a standard naming convention of `template.yaml`. In this example, you have two template files - one to create the example database and another to create the app itself. Save them in separate sub-directories in your project folder.

This AWS SAM template defines the resources for your app. We define the Lambda function using the `AWS::Serverless::Function` resource. The EventBridge Scheduler schedule and the trigger to invoke the Lambda function are created by using the `Events` property of this resource using a type of `ScheduleV2`. To learn more about defining EventBridge Scheduler schedules in AWS SAM templates, see [ScheduleV2](#) in the *AWS Serverless Application Model Developer Guide*.

In addition to the Lambda function and the EventBridge Scheduler schedule, we also define a CloudWatch log group for your function to send records of deleted items to.

Test script

Copy and paste the following code into a file named `test_app.py`.

```
import boto3  
from datetime import datetime, timedelta  
import json  
  
# Initialize the DynamoDB client  
dynamodb = boto3.resource('dynamodb')  
  
# Specify your table name  
table_name = 'YourTableName'  
table = dynamodb.Table(table_name)  
  
# Get the current date  
current_date = datetime.now()  
  
# Calculate the date one year ago  
one_year_ago = current_date - timedelta(days=365)
```

```

# Convert the date to string format (assuming the date in DynamoDB is stored as a
string)
one_year_ago_str = one_year_ago.strftime('%Y-%m-%d')

# Scan the table
response = table.scan(
    FilterExpression='#date < :one_year_ago',
    ExpressionAttributeNames={
        '#date': 'Date'
    },
    ExpressionAttributeValues={
        ':one_year_ago': one_year_ago_str
    }
)

# Process the results
old_records = response['Items']

# Continue scanning if we have more items (pagination)
while 'LastEvaluatedKey' in response:
    response = table.scan(
        FilterExpression='#date < :one_year_ago',
        ExpressionAttributeNames={
            '#date': 'Date'
        },
        ExpressionAttributeValues={
            ':one_year_ago': one_year_ago_str
        },
        ExclusiveStartKey=response['LastEvaluatedKey']
    )
    old_records.extend(response['Items'])

for record in old_records:
    print(json.dumps(record))

# The total number of old records should be zero.
print(f"Total number of old records: {len(old_records)}")

```

This test script uses the AWS SDK for Python (Boto3) to create a connection to your DynamoDB table and scan for items older than one year. To confirm if the Lambda function has run successfully, at the end of the test, the function prints the number of records older than one year still in the table. If the Lambda function was successful, the number of old records in the table should be zero.

Creating and populating the example DynamoDB table

To test your scheduled-maintenance app, you first create a DynamoDB table and populate it with some sample data. You can create the table either manually using the AWS Management Console or by using AWS SAM. We recommend that you use AWS SAM to quickly create and configure the table using a few AWS CLI commands.

Console

To create the DynamoDB table

1. Open the [Tables](#) page of the DynamoDB console.
2. Choose **Create table**.
3. Create the table by doing the following:
 - a. Under **Table details**, for **Table name**, enter **MyOrderTable**.
 - b. For **Partition key**, enter **Order_number** and leave the type as **String**.
 - c. For **Sort key**, enter **Date** and leave the type as **String**.
 - d. Leave **Table settings** set to **Default settings** and choose **Create table**.
4. When your table has finished creating and its **Status** shows as **Active**, create a global secondary index (GSI) by doing the following. Your app will use this GSI to search for items directly by date to determine what to delete.
 - a. Choose **MyOrderTable** from the list of tables.
 - b. Choose the **Indexes** tab.
 - c. Under **Global secondary indexes**, choose **Create index**.
 - d. Under **Index details**, enter **Date** for the **Partition key** and leave the **Data type** set to **String**.
 - e. For **Index name**, enter **Date-index**.
 - f. Leave all other parameters set to their default values, scroll to the bottom of the page, and choose **Create index**.

AWS SAM

To create the DynamoDB table

1. Navigate to the folder you saved the `template.yaml` file for the DynamoDB table in. Note that this example uses two `template.yaml` files. Make sure they are saved in separate sub-folders and that you are in the correct folder containing the template to create your DynamoDB table.
2. Run the following command.

```
sam build
```

This command gathers the build artifacts for the resources you want to deploy and places them in the proper format and location to deploy them.

3. To create the DynamoDB resource specified in the `template.yaml` file, run the following command.

```
sam deploy --guided
```

Using the `--guided` flag means that AWS SAM will show you prompts to guide you through the deployment process. For this deployment, enter a Stack name of **cron-app-test-db**, and accept the defaults for all other options by using Enter.

When AWS SAM has finished creating the DynamoDB resource, you should see the following message.

```
Successfully created/updated stack - cron-app-test-db in us-west-2
```

4. You can additionally confirm that the DynamoDB table has been created by opening the [Tables](#) page of the DynamoDB console. You should see a table named `MyOrderTable`.

After you've created your table, you next add some sample data to test your app. The CSV file `sample_data.csv` you downloaded earlier contains a number of example entries comprised of order numbers, dates, and customer and order information. Use the provided python script `load_sample_data.py` to add this data to your table.

To add the sample data to the table

1. Navigate to the directory containing the `sample_data.csv` and `load_sample_data.py` files. If these files are in separate directories, move them so they're saved in the same location.
2. Create a Python virtual environment to run the script in by running the following command. We recommend that you use a virtual environment because in a following step you'll need to install the AWS SDK for Python (Boto3).

```
python -m venv venv
```

3. Activate the virtual environment by running the following command.

```
source venv/bin/activate
```

4. Install the SDK for Python (Boto3) in your virtual environment by running the following command. The script uses this library to connect to your DynamoDB table and add the items.

```
pip install boto3
```

5. Run the script to populate the table by running the following command.

```
python load_sample_data.py
```

If the script runs successfully, it should print each item to the console as it loads it and report `Data loading completed`.

6. Deactivate the virtual environment by running the following command.

```
deactivate
```

7. You can verify that the data has been loaded to your DynamoDB table by doing the following:
 - a. Open the [Explore items](#) page of the DynamoDB console and select your table (MyOrderTable).
 - b. In the **Items returned** pane, you should see the 25 items from the CSV file that the script added to the table.

Creating the scheduled-maintenance app

You can create and deploy the resources for this example app step by step using the AWS Management Console or by using AWS SAM. In a production environment, we recommend that you use an Infrastructure-as-Code (IaC) tool like AWS SAM to repeatably deploy serverless applications without using manual processes.

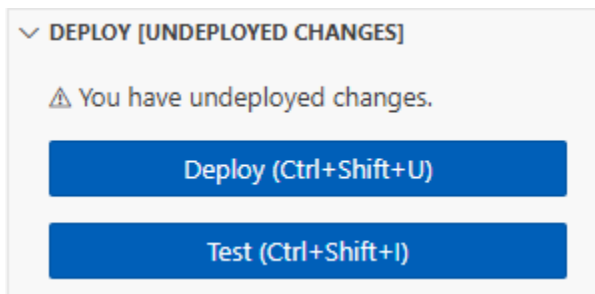

For this example, follow the console instructions to learn how to configure each AWS resource separately, or follow the AWS SAM instructions to quickly deploy the app using AWS CLI commands.

Console

To create the function using the AWS Management Console

First, create a function containing basic starter code. You then replace this code with your own function code by either copying and pasting the code directly in the Lambda code editor, or by uploading your code as a .zip package. For this task, we recommend copying and pasting the code.

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Choose **Author from scratch**.
4. Under **Basic information**, do the following:
 - a. For **Function name**, enter **ScheduledDBMaintenance**.
 - b. For **Runtime** choose the latest Python version.
 - c. For **Architecture**, choose **x86_64**.
5. Choose **Create function**.
6. After your function is created, you can configure your function with the provided function code.
 - a. In the **Code source** pane, replace the Hello world code that Lambda created with the Python function code from the `lambda_function.py` file that you saved earlier.
 - b. In the **DEPLOY** section, choose **Deploy** to update your function's code:

To configure the function memory and timeout (console)

1. Select the **Configuration** tab for your function.
2. In the **General configuration** pane, choose **Edit**.
3. Set **Memory** to 256 MB and **Timeout** to 15 seconds. If you are processing a large table with many records, for example in the case of a production environment, you might consider setting **Timeout** to a larger number. This gives your function more time to scan, and clean the database.
4. Choose **Save**.

To configure the log format (console)

You can configure Lambda functions to output logs in either unstructured text or JSON format. We recommend that you use JSON format for logs to make it easier to search and filter log data. To learn more about Lambda log configuration options, see [the section called “Configuring advanced logging controls for Lambda functions”](#).

1. Select the **Configuration** tab for your function.
2. Select **Monitoring and operations tools**.
3. In the **Logging configuration** pane, choose **Edit**.
4. For **Logging configuration**, select **JSON**.
5. Choose **Save**.

To set Up IAM permissions

To give your function the permissions it needs to read and delete DynamoDB items, you need to add a policy to your function's [execution role](#) defining the necessary permissions.

1. Open the **Configuration** tab, then choose **Permissions** from the left navigation bar.
2. Choose the role name under **Execution role**.
3. In the IAM console, choose **Add permissions**, then **Create inline policy**.
4. Use the JSON editor and enter the following policy:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "dynamodb:Scan",
        "dynamodb:DeleteItem",
        "dynamodb:BatchWriteItem"
      ],
      "Resource": "arn:aws:dynamodb:*:*:table/MyOrderTable"
    }
  ]
}
```

5. Name the policy **DynamoDBCleanupPolicy**, then create it.

To set up EventBridge Scheduler as a trigger (console)

1. Open the [EventBridge console](#).
2. In the left navigation pane, choose **Schedulers** under the **Scheduler** section.
3. Choose **Create schedule**.
4. Configure the schedule by doing the following:
 - a. Under **Schedule name**, enter a name for your schedule (for example, **DynamoDBCleanupSchedule**).
 - b. Under **Schedule pattern**, choose **Recurring schedule**.
 - c. For **Schedule type** leave the default as **Cron-based schedule**, then enter the following schedule details:
 - **Minutes:** 0
 - **Hours:** 3

- **Day of month:** 1
- **Month:** *
- **Day of the week:** ?
- **Year:** *

When evaluated, this cron expression runs on the first day of every month at 03:00 AM.

- d. For **Flexible time window**, select **Off**.
5. Choose **Next**.
6. Configure the trigger for your Lambda function by doing the following:
 - a. In the **Target detail** pane, leave **Target API** set to **Templated targets**, then select **AWS Lambda Invoke**.
 - b. Under **Invoke**, select your Lambda function (ScheduledDBMaintenance) from the dropdown list.
 - c. Leave the **Payload** empty and choose **Next**.
 - d. Scroll down to **Permissions** and select **Create a new role for this schedule**. When you create a new EventBridge Scheduler schedule using the console, EventBridge Scheduler creates a new policy with the required permissions the schedule needs to invoke your function. For more information about managing your schedule permissions, see [Cron-based schedules](#) in the *EventBridge Scheduler User Guide*.
 - e. Choose **Next**.
7. Review your settings and choose **Create schedule** to complete creation of the schedule and Lambda trigger.

AWS SAM

To deploy the app using AWS SAM

1. Navigate to the folder you saved the `template.yaml` file for the app in. Note that this example uses two `template.yaml` files. Make sure they are saved in separate sub-folders and that you are in the correct folder containing the template to create the app.
2. Copy the `lambda_function.py` and `requirements.txt` files you downloaded earlier to the same folder. The code location specified in the AWS SAM template is `./`, meaning

the current location. AWS SAM will search in this folder for the Lambda function code when you try to deploy the app.

3. Run the following command.

```
sam build --use-container
```

This command gathers the build artifacts for the resources you want to deploy and places them in the proper format and location to deploy them. Specifying the `--use-container` option builds your function inside a Lambda-like Docker container. We use it here so you don't need to have Python 3.12 installed on your local machine for the build to work.

4. To create the Lambda and EventBridge Scheduler resources specified in the `template.yaml` file, run the following command.

```
sam deploy --guided
```

Using the `--guided` flag means that AWS SAM will show you prompts to guide you through the deployment process. For this deployment, enter a Stack name of **cron-maintenance-app**, and accept the defaults for all other options by using Enter.

When AWS SAM has finished creating the Lambda and EventBridge Scheduler resources, you should see the following message.

```
Successfully created/updated stack - cron-maintenance-app in us-west-2
```

5. You can additionally confirm that the Lambda function has been created by opening the [Functions](#) page of the Lambda console. You should see a function named `ScheduledDBMaintenance`.

Testing the app

To test that your schedule correctly triggers your function, and that your function correctly cleans records from the database, you can temporarily modify your schedule to run once at a specific time. You can then run `sam deploy` again to reset your recurrence schedule to run once a month.

To run the application using the AWS Management Console

1. Navigate back to the EventBridge Scheduler console page.

2. Choose your schedule, then choose **Edit**.
3. In the **Schedule pattern** section, under **Recurrence**, choose **One-time schedule**.
4. Set your invocation time to a few minutes from now, review your settings, then choose **Save**.

After the schedule runs and invokes its target, you run the `test_app.py` script to verify that your function successfully removed all old records from the DynamoDB table.

To verify that old records are deleted using a Python script

1. In your command line, navigate to the folder where you saved `test_app.py`.
2. Run the script.

```
python test_app.py
```

If successful, you will see the following output.

```
Total number of old records: 0
```

Next steps

You can now modify the EventBridge Scheduler schedule to meet your particular application requirements. EventBridge Scheduler supports the following schedule expressions: cron, rate, and one-time schedules.

For more information about EventBridge Scheduler schedule expressions, see [Schedule types](#) in the *EventBridge Scheduler User Guide*. [Access Management](#) in the *IAM User Guide*

Creating an Order Processing System with Lambda Durable Functions

Note

NEED: Add architecture diagram showing API Gateway, Durable Function workflow, and supporting services (DynamoDB, EventBridge)

Prerequisites

- AWS CLI installed and configured
- NEED: Specific Durable Functions requirements

Create the Source Code Files

Create the following files in your project directory:

- `lambda_function.py` - the function code
- `requirements.txt` - dependencies manifest

Function Code

```
# NEED: Verify correct imports
import boto3
import json

def lambda_handler(event, context):
    # NEED: Verify DurableContext syntax
    durable = context.durable

    try:
        # Validate and store order
        order = await durable.step('validate', async () => {
            return validate_order(event['order'])
        })

        # Process payment
        # NEED: Verify wait syntax
        await durable.wait(/* wait configuration */)

        # Additional steps
        # NEED: Complete implementation

    except Exception as e:
        # NEED: Error handling patterns
        raise e

def validate_order(order_data):
```

```
# NEED: Implementation  
pass
```

Requirements File

```
# NEED: List of required packages
```

Deploy the App

Create a DynamoDB Table for Orders

1. Open the DynamoDB console at <https://console.aws.amazon.com/dynamodb/>
2. Choose **Create table**
3. For **Table name**, enter **Orders**
4. For **Partition key**, enter **orderId**
5. Leave other settings as default
6. Choose **Create table**

Create the Lambda Function

1. Open the Lambda console at <https://console.aws.amazon.com/lambda/>
2. Choose **Create function**
3. Select **Author from scratch**
4. For **Function name**, enter **ProcessOrder**
5. For **Runtime**, choose your preferred runtime
6. NEED: Add Durable Functions-specific configuration
7. Choose **Create function**

Create the API Gateway Endpoint

1. Open the API Gateway console at <https://console.aws.amazon.com/apigateway/>
2. Choose **Create API**
3. Select **HTTP API**
4. Choose **Build**

5. Add an integration with your Lambda function
6. Configure routes for order processing
7. Deploy the API

Test the App

Submit a test order:

```
{
  "orderId": "12345",
  "items": [
    {
      "productId": "ABC123",
      "quantity": 1
    }
  ]
}
```

NEED: Add specific monitoring instructions for Durable Functions

Next Steps

Add Business Logic

Implement inventory management:

```
async def check_inventory(order):
    # Add inventory check logic
    pass
```

Add price calculations:

```
async def calculate_total(order):
    # Add pricing logic
    pass
```

Improve Error Handling

Add compensation logic:

```
async def reverse_payment(order):  
    # Add payment reversal logic  
    pass
```

Handle order cancellations:

```
async def cancel_order(order):  
    # Add cancellation logic  
    pass
```

Integrate External Systems

```
async def notify_shipping_provider(order):  
    # Add shipping integration  
    pass  
  
async def send_customer_notification(order):  
    # Add notification logic  
    pass
```

Enhance Monitoring

- Create CloudWatch dashboards
- Set up metrics for order processing times
- Configure alerts for delayed orders

Development tools for Lambda

You have access to a variety of tools that increase productivity and ease-of-use throughout the entire development lifecycle. This section provides information on tools that help many Lambda customers design, develop, and manage their applications. From local development in your IDE to deploying and managing complex serverless applications, these tools help you streamline your workflow, improve code quality, and accelerate the development of robust Lambda-based solutions.

- **Local development**—Write and test Lambda functions faster in your preferred development environment. The AWS Toolkit for VS Code enables local function development, debugging, and testing with direct deployment capabilities to Lambda.
- **Infrastructure as Code (IaC)**—Deploy and manage serverless applications consistently from local testing to production. AWS SAM, AWS CDK, and CloudFormation let you define and manage your serverless infrastructure through code for consistent, version-controlled deployments.
- **GitHub Actions**—Automate Lambda deployments directly from your code repository. GitHub Actions allows you to set up workflows that automatically deploy your Lambda functions whenever you push code or configuration changes, simplifying your CI/CD pipeline.
- **Powertools for AWS Lambda**—Build production-ready serverless applications with less custom code. Powertools for AWS Lambda (also referred to as Powertools for AWS) is an open-source developer toolkit that simplifies implementing serverless best practices such as observability, parameter retrieval, and idempotency across Python, TypeScript, Java, and .NET.
- **Workflows and events**—Coordinate Lambda functions with AWS services, APIs, and external systems. Lambda provides two orchestration options: [Lambda durable functions](#) for application-centric orchestration using standard programming languages within Lambda, and [AWS Step Functions](#) for workflow-centric orchestration with visual design across multiple services. Amazon EventBridge provides event management capabilities for event-driven architectures. For help choosing an orchestration approach, see [Durable functions or Step Functions](#).

Local development tools

Local development environments enable you to work offline and leverage advanced IDE features while iterating quickly on your Lambda functions. These tools help you debug complex functions and develop in environments with limited connectivity. They also support team collaboration and integration with version control systems.

For more information on developing Lambda functions locally, see [Developing Lambda functions locally with VS Code](#). This page describes how to move Lambda function development from the AWS console to Visual Studio Code, which provides a rich development environment with features like debugging and code completion. To make the transition, you need to set up the AWS Toolkit for Visual Studio Code and credentials, after which you can use advanced features in VS Code while maintaining the ability to deploy directly to AWS.

Local development for Lambda provides several key capabilities:

- Use Visual Studio Code integration with the Lambda console
- Configure local Lambda development environments
- Debug and test functions locally
- Apply best practices for local function management

For more information, see [Developing Lambda functions locally with VS Code](#).

Infrastructure as Code (IaC) tools

With Infrastructure as Code (IaC) tools, you can define and manage your serverless architecture using code. This approach helps maintain consistency across environments, lets you control your infrastructure versions, and facilitates DevOps practices. IaC is especially valuable for automating deployments, ensuring consistent environments, and managing multi-region deployments.

Key IaC tools and concepts for Lambda include frameworks for template creation, deployment management, and best practices for serverless infrastructure:

- Core IaC principles for Lambda development
- CloudFormation, AWS SAM, and AWS CDK capabilities
- Tool selection criteria and comparison
- Best practices for Lambda IaC implementation

Whether you're working independently on a small project or as part of a large team managing enterprise-scale serverless applications, these development and deployment tools can help you write, deploy, and manage your Lambda functions more effectively.

For more information, see [Using Lambda with infrastructure as code \(IaC\)](#).

GitHub Actions tools

GitHub Actions provides automated deployment capabilities for your Lambda functions directly from your code repository. By creating workflow files in your repository, you can automatically deploy Lambda functions whenever code or configuration changes are pushed, streamlining your continuous integration and continuous deployment (CI/CD) pipeline. The Deploy Lambda Function action offers a declarative YAML interface that simplifies the deployment process, handles AWS credentials through OpenID Connect (OIDC), and supports various deployment scenarios including code updates, configuration changes, and dry run validations. This integration enables teams to maintain a consistent and automated deployment process while leveraging their existing GitHub workflows.

For more information, see [Using GitHub Actions to deploy Lambda functions](#).

Powertools for AWS Lambda

Powertools for AWS is an open-source developer toolkit that helps you implement serverless best practices with minimal custom code. Available for Python, TypeScript/Node.js, Java, and .NET, it provides utility functions, decorators, and middleware that streamline common Lambda development tasks. The toolkit includes built-in observability features like structured logging, tracing, and metrics collection, such as utilities for parameter retrieval, secrets management, and idempotency patterns. These tools align with AWS well-architected best practices and help developers build production-ready serverless applications more efficiently. By reducing boilerplate code and standardizing common patterns, Powertools for AWS enables teams to focus on business logic while maintaining consistent implementation of serverless best practices across their applications.

For more information, see [Powertools for AWS Lambda](#).

Workflow and event management tools

Lambda applications can be used in orchestration of complex workflows and handling of various events. AWS provides specialized tools to help you manage these aspects of serverless development. Learn about AWS Step Functions for workflow orchestration and Amazon EventBridge for event management, and how to integrate them with your Lambda functions. These tools can significantly enhance the scalability and reliability of your serverless applications by providing robust state management and event-driven architectures. By leveraging these

services, you can build more sophisticated and resilient Lambda-based solutions that can handle complex business processes and react to a wide range of system and application events.

For more information, see [Managing Lambda workflows and events](#).

Developing Lambda functions locally with VS Code

You can move your Lambda functions from the Lambda console to Visual Studio Code, which provides a full development environment and allows you to use other local development options like AWS SAM and AWS CDK.

Key benefits of local development

While the Lambda console provides a quick way to edit and test functions, local development offers more advanced capabilities:

- **Advanced IDE features:** Debugging, code completion, and refactoring tools
- **Offline development:** Work and test changes locally before cloud deployment
- **Infrastructure as code integration:** Seamless use with AWS SAM, AWS CDK, and Infrastructure Composer
- **Dependency management:** Full control over function dependencies

Prerequisites

Before developing Lambda functions locally in VS Code, you must have:

- **VS Code:** For installation instructions, see [Download VS Code](#).
- **AWS Toolkit for Visual Studio Code:** For installation instructions, see [Setting up the AWS Toolkit for Visual Studio Code](#). For an overview, see [AWS Toolkit for Visual Studio Code](#).
- **AWS credentials:** For information about configuring credentials, see [Setting up your AWS credentials](#).
- **AWS SAM CLI:** For installation instructions, see [Installing the AWS SAM CLI](#).
- **Docker installed (optional, but required for local testing):** For installation instructions, see [Get Docker](#).

Note

If you already have an AWS account and profile configured locally, ensure that the AdministratorAccess managed policy is added to your configured AWS profile.

Authentication and access control

To develop Lambda functions locally, you need AWS credentials to securely access and manage AWS resources on your behalf, just like they would in the cloud. The AWS Toolkit for VS Code supports the following authentication methods:

The AWS Toolkit for VS Code supports the following authentication methods:

- IAM user long-term credentials
- Temporary credentials from assumed roles
- Identity federation
- AWS account root user credentials (not recommended)

This section guides you through obtaining and configuring these credentials using IAM user long-term credentials.

Get IAM Credentials

If you already have an IAM user with access keys, have both the access key ID and secret access key ready for the next section. If you don't have these keys, follow these steps to create them:

Note

You must use both the access key ID and secret access key together to authenticate your requests.

To create an IAM user and access keys:

1. Open the IAM console at <https://console.aws.amazon.com/iam/>
2. In the navigation pane, choose **Users**.

3. Choose **Create user**.
4. For **User name**, enter a name and choose **Next**.
5. Under **Set permissions**, choose **Attach policies directly**.
6. Select **AdministratorAccess** and choose **Next**.
7. Choose **Create user**.
8. In the success banner, choose **View user**.
9. Choose **Create access key**.
- 10 For **Use case**, select **Local code**.
- 11 Select the confirmation check box and choose **Next**.
- 12 (Optional) Enter a description tag value.
- 13 Choose **Create access key**.
- 14 Copy your access key and secret access key immediately. **You won't be able to access the secret access key again after you leave this page.**

Important

Never share your secret key or commit it to source control. Store these keys securely and delete them when no longer needed.

Note

For more information, see [Create an IAM user in your AWS account](#) and [Manage access keys for IAM users](#) in the *IAM User Guide*.

Configure AWS credentials using the AWS Toolkit

The following table summarizes the credential setup process you will complete in the following procedure.

What to Do	Why?
Open Sign In panel	Start authentication

What to Do	Why?
Use Command Palette, search for AWS Add a New Connection	Access the sign-in UI
Choose IAM Credential	Use your access keys for programmatic access
Enter profile name, access key, secret key	Provide credentials for connection
See AWS Explorer update	Confirm you're connected

Complete the following steps authenticate to your AWS account:

1. Open the Sign In panel in VS Code:
 - a. To start the authentication process, select the AWS icon in the left navigation pane or open the Command Palette (Cmd+Shift+P on Mac or Ctrl+Shift+P on Windows/Linux) and search for and select **AWS Add a New Connection**.
2. In the sign in panel, choose **IAM Credentials** and select **Continue**.

 **Note**

To proceed, you will need to allow AWS IDE Extensions for VS Code to access your data.

3. Enter your profile name, access key ID, and secret access key, then select **Continue**.
4. Verify the connection by checking the AWS Explorer in VS Code for your AWS services and resources.

For information on setting up authentication with long-term credentials, see [Using long-term credentials to authenticate AWS SDKs and tools](#).

For information about configuring authentication, see [AWS IAM credentials](#) in the AWS Toolkit for Visual Studio Code User Guide.

Moving from console to local development

Note

If you've made changes in the console, make sure you don't have any undeployed changes before transitioning to local development.

To move a Lambda function from the Lambda console to VS Code, complete the following steps:

1. Open the [Lambda console](#).
2. Choose the name of your function.
3. Select the **Code source** tab.
4. Choose **Open in Visual Studio Code**.

Note

The **Open in Visual Studio Code** button is only available in AWS Toolkit version **3.69.0** and later. If you have an earlier version of the AWS Toolkit installed, you may see a `Cannot open the handler` message in VS Code. To resolve this, update your AWS Toolkit to the latest version.

5. When prompted, allow your browser to open VS Code.

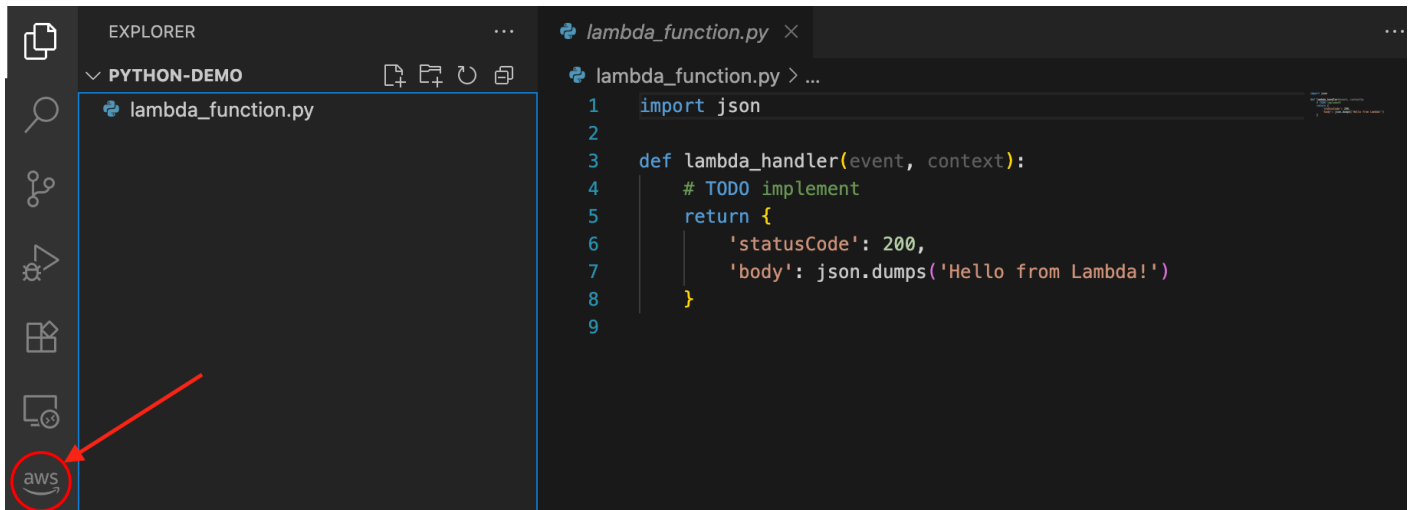

When you open your function in VS Code, Lambda creates a local project with your function code in a temporary location that's designed for quick testing and deployment. This includes the function code, dependencies, and a basic project structure that you can use for local development.

For details on using AWS in VS Code, see the [AWS Toolkit for Visual Studio Code User Guide](#).

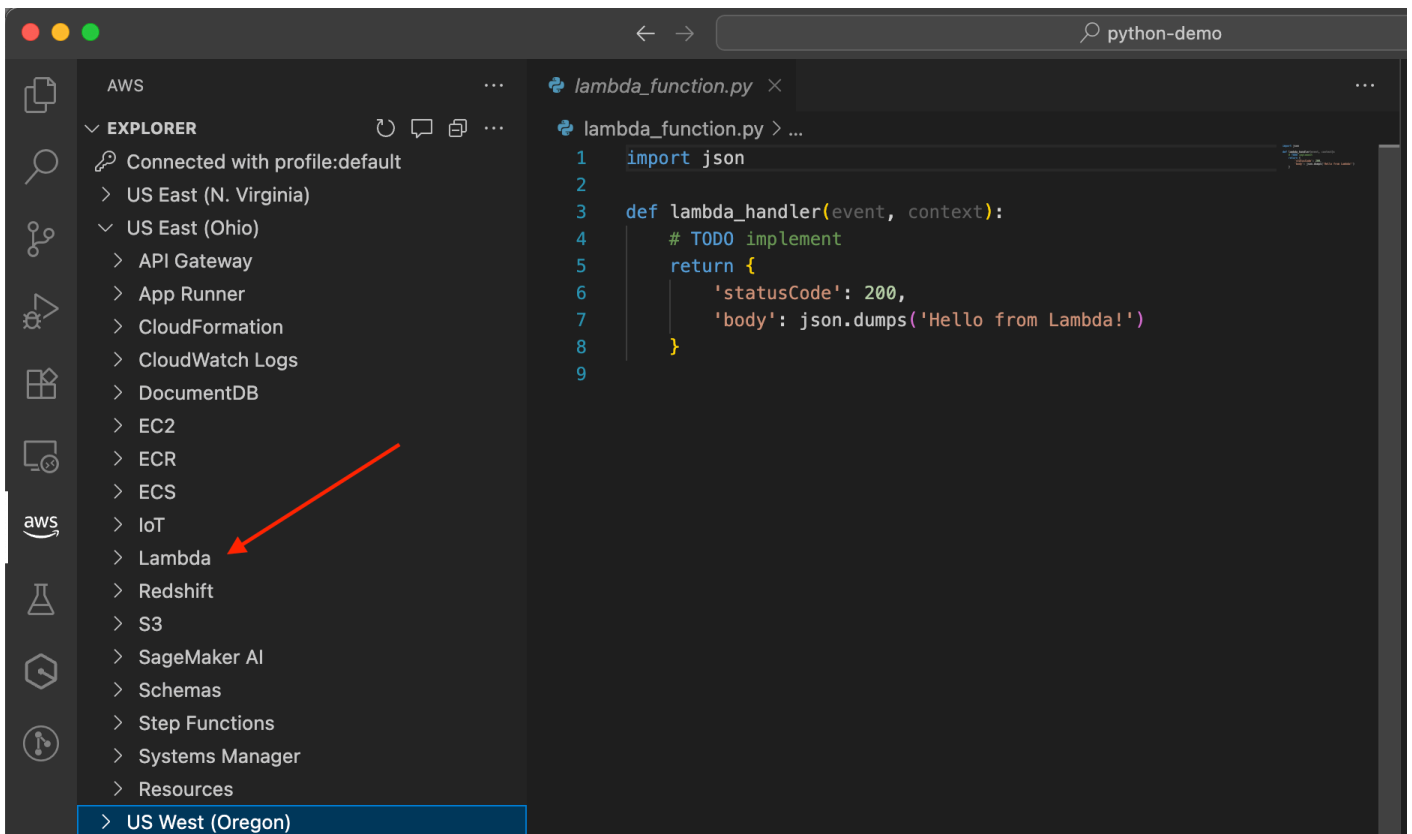

Working with functions locally

After opening your function in VS Code, follow these steps to access and manage your functions:

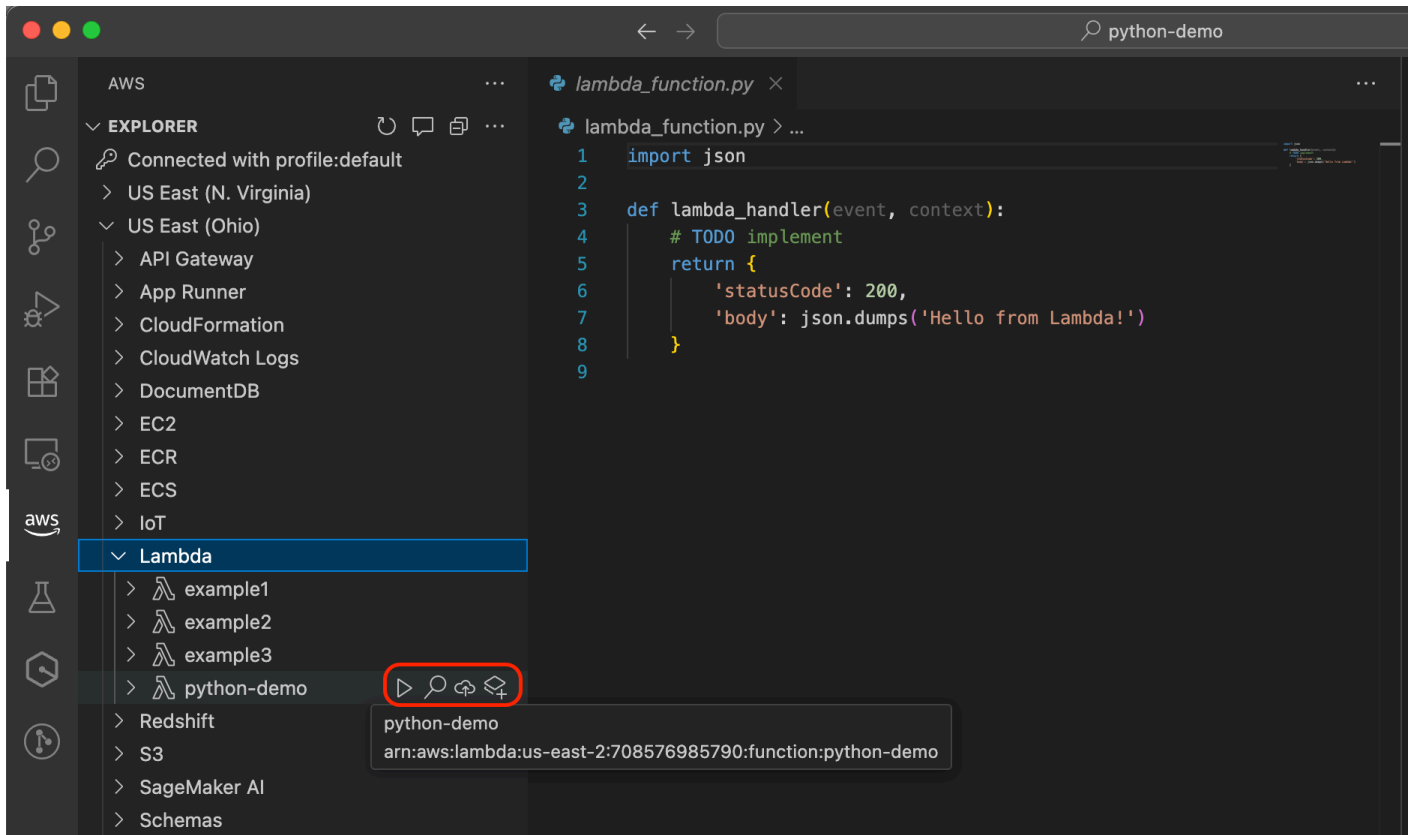

1. Select the AWS icon in the sidebar to open the AWS Explorer:

2. In the AWS Explorer, select the region with your Lambda function:

3. Under your selected region, expand the Lambda section to view and manage your functions:

With your function opened in VS Code, you can:

- Edit function code with full language support and code completion.
- Use the [LocalStack integration in VS Code](#) to test Lambda functions that make API calls to other AWS services during execution, such as reading from DynamoDB tables or writing to Amazon S3 buckets. LocalStack is a cloud service emulator that provides a complete local development environment for testing service integrations. You can also [use AWS SAM CLI to test your function in a local container](#). If your function makes API calls to other AWS services those calls will reach real AWS resources, not emulated ones.
- Debug your function with breakpoints and variable inspection. For more information, see [Running and debugging Lambda functions directly from code](#) in the *AWS Toolkit for Visual Studio Code User Guide*.
- Deploy your updated function back to AWS using the cloud icon.
- Install and manage dependencies for your function.

For more information, see [Working with AWS Lambda functions](#) in the AWS Toolkit for Visual Studio Code User Guide.

Convert your function to an AWS SAM template and use IaC tools

In VS Code, you can convert your Lambda function to an AWS SAM template by choosing the **Convert to AWS SAM Application** icon next to your Lambda function. You will be prompted to select an AWS SAM project location. Once selected, your Lambda function will be converted to a `template.yaml` file that is saved in your new AWS SAM project.

With your function converted to an AWS SAM template, you can:

- Control the versioning of your infrastructure
- Automate deployments
- Remotely debug functions
- Add additional AWS resources to your application
- Maintain consistent environments across your development lifecycle
- Use Infrastructure Composer to visually edit your AWS SAM template

For more information on using IaC tools, refer to the following guides:

- [The AWS Serverless Application Model Developer Guide](#)
- [The AWS Cloud Development Kit \(AWS CDK\) Developer Guide](#)
- [The Infrastructure Composer Developer Guide](#)
- [The AWS CloudFormation User Guide](#)

These tools provide additional capabilities for defining, testing, and deploying your serverless applications.

Next steps

To learn more about working with Lambda functions in VS Code, see the following resources:

- [Working with AWS Lambda functions](#) in the AWS Toolkit for VS Code User Guide
- [Working with serverless applications](#) in the AWS Toolkit for VS Code User Guide

- [Infrastructure as code](#) in the Lambda Developer Guide

Using GitHub Actions to deploy Lambda functions

You can use [GitHub Actions](#) to automatically deploy Lambda functions when you push code or configuration changes to your repository. The [Deploy Lambda Function](#) action provides a declarative, simple YAML interface that eliminates the complexity of manual deployment steps.

Example workflow

To configure automated Lambda function deployment, create a workflow file in your repository's `.github/workflows/` directory:

Example GitHub Actions workflow for Lambda deployment

```
name: Deploy AWS Lambda

on:
  push:
    branches:
      - main

jobs:
  deploy:
    runs-on: ubuntu-latest
    permissions:
      id-token: write # Required for OIDC authentication
      contents: read # Required to check out the repository
    steps:
      - uses: actions/checkout@v4

      - name: Configure AWS credentials
        uses: aws-actions/configure-aws-credentials@v4
        with:
          role-to-assume: arn:aws:iam::123456789012:role/GitHubActionRole
          aws-region: us-east-1

      - name: Deploy Lambda Function
        uses: aws-actions/aws-lambda-deploy@v1
        with:
          function-name: my-lambda-function
```

```
code-artifacts-dir: ./dist
```

This workflow runs when you push changes to the main branch. It checks out your repository, configures AWS credentials using OpenID Connect (OIDC), and deploys your function using the code in the `./dist` directory.

For additional examples including updating function configuration, deploying via S3 buckets, and dry run validation, see the [Deploy Lambda Function README](#).

Additional resources

- [Configure AWS Credentials GitHub Action](#)
- [Configuring OpenID Connect in AWS](#)

Using Lambda with infrastructure as code (IaC)

Lambda functions rarely run in isolation. Instead, they often form part of a serverless application with other resources such as databases, queues, and storage. With [infrastructure as code \(IaC\)](#), you can automate your deployment processes to quickly and repeatably deploy and update whole serverless applications involving many separate AWS resources. This approach speeds up your development cycle, makes configuration management easier, and ensures that your resources are deployed the same way every time.

IaC tools for Lambda

CloudFormation

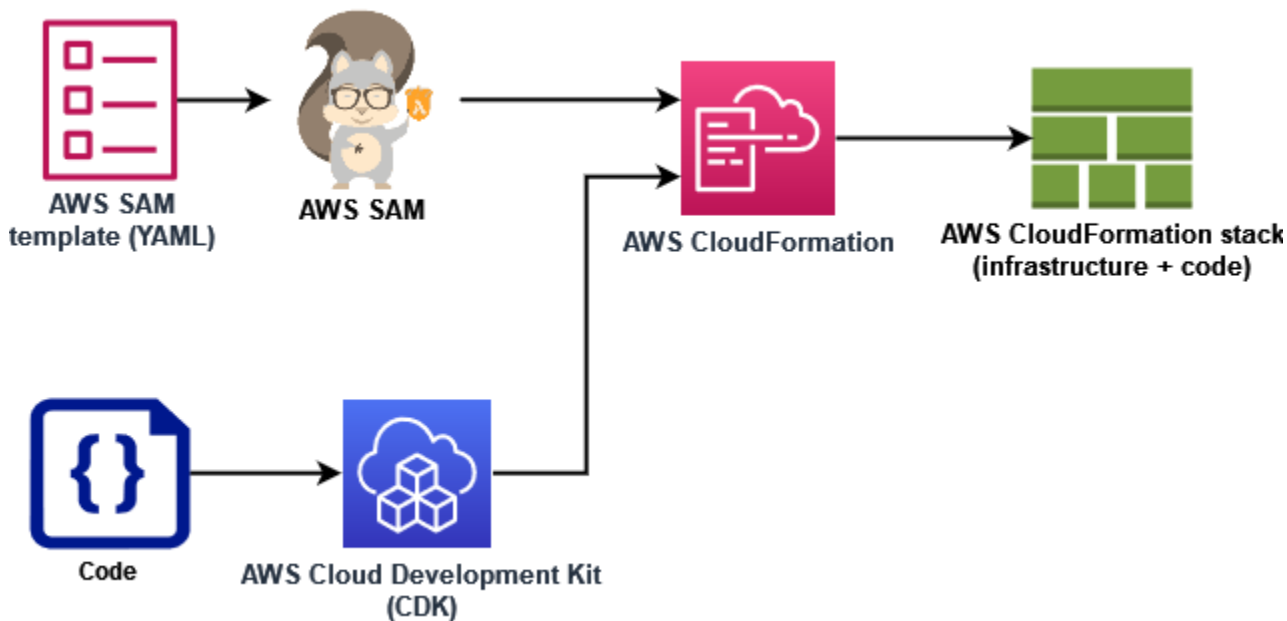

CloudFormation is the foundational IaC service from AWS. You can use [YAML or JSON templates](#) to model and provision your entire AWS infrastructure, including Lambda functions. CloudFormation handles the complexities of creating, updating, and deleting your AWS resources.

AWS Serverless Application Model (AWS SAM)

AWS SAM is an open-source framework built on top of CloudFormation. It provides a simplified syntax for defining serverless applications. Use [AWS SAM templates](#) to quickly provision Lambda functions, APIs, databases, and event sources with just a few lines of YAML.

AWS Cloud Development Kit (AWS CDK)

The CDK is a code-first approach to IaC. You can define your Lambda-based architecture using TypeScript, JavaScript, Python, Java, C#/.Net, or Go. Choose your preferred language and use programming elements like parameters, conditionals, loops, composition, and inheritance to define the desired outcome of your infrastructure. The CDK then generates the underlying CloudFormation templates for deployment. For an example of how to use Lambda with CDK, see [Deploying Lambda functions with AWS CDK](#).

AWS also provides a service called AWS Infrastructure Composer to develop IaC templates using a simple graphical interface. With Infrastructure Composer, you design an application architecture by dragging, grouping, and connecting AWS services in a visual canvas. Infrastructure Composer then creates an AWS SAM template or an CloudFormation template from your design that you can use to deploy your application.

In the [the section called “Using AWS SAM and Infrastructure Composer”](#) section below, you use Infrastructure Composer to develop a template for a serverless application based on an existing Lambda function.

Using Lambda functions in AWS SAM and Infrastructure Composer

In this tutorial, you can get started using IaC with Lambda by creating an AWS SAM template from an existing Lambda function and then building out a serverless application in Infrastructure Composer by adding other AWS resources.

As you carry out this tutorial, you'll learn some fundamental concepts, like how AWS resources are specified in AWS SAM. You'll also learn how to use Infrastructure Composer to build a serverless application you can deploy using AWS SAM or CloudFormation.

To complete this tutorial, you'll carry out the following steps:

- Create an example Lambda function
- Use the Lambda console to view the AWS SAM template for the function
- Export your function's configuration to AWS Infrastructure Composer and design a simple serverless application based on your function's configuration
- Save an updated AWS SAM template you can use as a basis to deploy your serverless application

Prerequisites

In this tutorial, you use Infrastructure Composer's [local sync](#) feature to save your template and code files to your local build machine. To use this feature, you need a browser that supports the File System Access API, which allows web applications to read, write, and save files in your local file system. We recommend using either Google Chrome or Microsoft Edge. For more information about the File System Access API, see [What is the File System Access API?](#)

Create a Lambda function

In this first step, you create a Lambda function you can use to complete the rest of the tutorial. To keep things simple, you use the Lambda console to create a basic 'Hello world' function using the Python 3.11 runtime.

To create a 'Hello world' Lambda function using the console

1. Open the [Lambda console](#).
2. Choose **Create function**.
3. Leave **Author from scratch** selected, and under **Basic information**, enter **LambdaIaCDemo** for **Function name**.

4. For **Runtime**, select **Python 3.11**.
5. Choose **Create function**.

View the AWS SAM template for your function

Before you export your function configuration to Infrastructure Composer, use the Lambda console to view your function's current configuration as an AWS SAM template. By following the steps in this section, you'll learn about the anatomy of an AWS SAM template and how to define resources like Lambda functions to start specifying a serverless application.

To view the AWS SAM template for your function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function you just created (LambdaIaCDemo).
3. In the **Function overview** pane, choose **Template**.

In place of the diagram representing your function's configuration, you'll see an AWS SAM template for your function. The template should look like the following.

```
# This AWS SAM template has been generated from your function's
# configuration. If your function has one or more triggers, note
# that the AWS resources associated with these triggers aren't fully
# specified in this template and include placeholder values. Open this template
# in AWS Application Composer or your favorite IDE and modify
# it to specify a serverless application with other AWS resources.
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: An AWS Serverless Specification template describing your function.
Resources:
  LambdaIaCDemo:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: .
      Description: ''
      MemorySize: 128
      Timeout: 3
      Handler: lambda_function.lambda_handler
      Runtime: python3.11
      Architectures:
        - x86_64
```

```
EventInvokeConfig:
  MaximumEventAgeInSeconds: 21600
  MaximumRetryAttempts: 2
EphemeralStorage:
  Size: 512
RuntimeManagementConfig:
  UpdateRuntimeOn: Auto
SnapStart:
  ApplyOn: None
PackageType: Zip
Policies:
  Statement:
    - Effect: Allow
      Action:
        - logs:CreateLogGroup
      Resource: arn:aws:logs:us-east-1:123456789012:*
    - Effect: Allow
      Action:
        - logs:CreateLogStream
        - logs:PutLogEvents
      Resource:
        - >-
          arn:aws:logs:us-east-1:123456789012:log-group:/aws/lambda/
LambdaIaCDemo:*
```

Let's take a moment to look at the YAML template for your function and understand some key concepts.

The template starts with the declaration `Transform: AWS::Serverless-2016-10-31`. This declaration is required because behind the scenes, AWS SAM templates are deployed through CloudFormation. Using the `Transform` statement identifies the template as an AWS SAM template file.

Following the `Transform` declaration comes the `Resources` section. This is where the AWS resources you want to deploy with your AWS SAM template are defined. AWS SAM templates can contain a combination of AWS SAM resources and CloudFormation resources. This is because during deployment, AWS SAM templates expand to CloudFormation templates, so any valid CloudFormation syntax can be added to an AWS SAM template.

At the moment, there is just one resource defined in the `Resources` section of the template, your Lambda function `LambdaIaCDemo`. To add a Lambda function to an AWS SAM template, you

use the `AWS::Serverless::Function` resource type. The Properties of a Lambda function resource define the function's runtime, function handler, and other configuration options. The path to your function's source code that AWS SAM should use to deploy the function is also defined here. To learn more about Lambda function resources in AWS SAM, see [AWS::Serverless::Function](#) in the *AWS SAM Developer Guide*.

As well as the function properties and configurations, the template also specifies an AWS Identity and Access Management (IAM) policy for your function. This policy gives your function permission to write logs to Amazon CloudWatch Logs. When you create a function in the Lambda console, Lambda automatically attaches this policy to your function. To learn more about specifying an IAM policy for a function in an AWS SAM template, see the `policies` property on the [AWS::Serverless::Function](#) page of the *AWS SAM Developer Guide*.

To learn more about the structure of AWS SAM templates, see [AWS SAM template anatomy](#).

Use AWS Infrastructure Composer to design a serverless application

To start building out a simple serverless application using your function's AWS SAM template as a starting point, you export your function configuration to Infrastructure Composer and activate Infrastructure Composer's local sync mode. Local sync automatically saves your function's code and your AWS SAM template to your local build machine and keeps your saved template synced as you add other AWS resources in Infrastructure Composer.

To export your function to Infrastructure Composer

1. In the **Function Overview** pane, choose **Export to Application Composer**.

To export your function's configuration and code to Infrastructure Composer, Lambda creates an Amazon S3 bucket in your account to temporarily store this data.

2. In the dialog box, choose **Confirm and create project** to accept the default name for this bucket and export your function's configuration and code to Infrastructure Composer.
3. (Optional) To choose another name for the Amazon S3 bucket that Lambda creates, enter a new name and choose **Confirm and create project**. Amazon S3 bucket names must be globally unique and follow the [bucket naming rules](#).

Selecting **Confirm and create project** opens the Infrastructure Composer console. On the *canvas*, you'll see your Lambda function.

4. From the **Menu** dropdown, choose **Activate local sync**.

5. In the dialog box that opens, choose **Select folder** and select a folder on your local build machine.
6. Choose **Activate** to activate local sync.

To export your function to Infrastructure Composer, you need permission to use certain API actions. If you're unable to export your function, see [the section called "Required permissions"](#) and make sure you have the permissions you need.

 **Note**

Standard [Amazon S3 pricing](#) applies for the bucket Lambda creates when you export a function to Infrastructure Composer. The objects that Lambda puts into the bucket are automatically deleted after 10 days, but Lambda doesn't delete the bucket itself. To avoid additional charges being added to your AWS account, follow the instructions in [Deleting a bucket](#) after you have exported your function to Infrastructure Composer. For more information about the Amazon S3 bucket Lambda creates, see [the section called "Infrastructure Composer"](#).

To design your serverless application in Infrastructure Composer

After activating local sync, changes you make in Infrastructure Composer will be reflected in the AWS SAM template saved on your local build machine. You can now drag and drop additional AWS resources onto the Infrastructure Composer canvas to build out your application. In this example, you add an Amazon SQS simple queue as a trigger for your Lambda function and a DynamoDB table for the function to write data to.

1. Add an Amazon SQS trigger to your Lambda function by doing the following:
 - a. In the search field in the **Resources** palette, enter **SQS**.
 - b. Drag the **SQS Queue** resource onto your canvas and position it to the left of your Lambda function.
 - c. Choose **Details**, and for **Logical ID** enter **LambdaIaCQueue**.
 - d. Choose **Save**.
 - e. Connect your Amazon SQS and Lambda resources by clicking on the **Subscription** port on the SQS queue card and dragging it to the left hand port on the Lambda function card. The appearance of a line between the two resources indicates a successful connection.

Infrastructure Composer also displays a message at the bottom of the canvas indicating that the two resources are successfully connected.

2. Add an Amazon DynamoDB table for your Lambda function to write data to by doing the following:
 - a. In the search field in the **Resources** palette, enter **DynamoDB**.
 - b. Drag the **DynamoDB Table** resource onto your canvas and position it to the right of your Lambda function.
 - c. Choose **Details**, and for **Logical ID** enter **LambdaIaCTable**.
 - d. Choose **Save**.
 - e. Connect the DynamoDB table to your Lambda function by clicking on the right hand port of the Lambda function card and dragging it to the left hand port on the DynamoDB card.

Now that you've added these extra resources, let's take a look at the updated AWS SAM template Infrastructure Composer has created.

To view your updated AWS SAM template

- On the Infrastructure Composer canvas, choose **Template** to switch from the canvas view to the template view.

Your AWS SAM template should now contain the following additional resources and properties:

- An Amazon SQS queue with the identifier LambdaIaCQueue

```
LambdaIaCQueue:
  Type: AWS::SQS::Queue
  Properties:
    MessageRetentionPeriod: 345600
```

When you add an Amazon SQS queue using Infrastructure Composer, Infrastructure Composer sets the `MessageRetentionPeriod` property. You can also set the `FifoQueue` property by selecting **Details** on the SQS Queue card and checking or unchecking **Fifo queue**.

To set other properties for your queue, you can manually edit the template to add them. To learn more about the `AWS::SQS::Queue` resource and its available properties, see [AWS::SQS::Queue](#) in the *CloudFormation User Guide*.

- An Events property in your Lambda function definition that specifies the Amazon SQS queue as a trigger for the function

```
Events:
  LambdaIaCQueue:
    Type: SQS
    Properties:
      Queue: !GetAtt LambdaIaCQueue.Arn
      BatchSize: 1
```

The Events property consists of an event type and a set of properties that depend on the type. To learn about the different AWS services you can configure to trigger a Lambda function and the properties you can set, see [EventSource](#) in the *AWS SAM Developer Guide*.

- A DynamoDB table with the identifier LambdaIaCTable

```
LambdaIaCTable:
  Type: AWS::DynamoDB::Table
  Properties:
    AttributeDefinitions:
      - AttributeName: id
        AttributeType: S
    BillingMode: PAY_PER_REQUEST
    KeySchema:
      - AttributeName: id
        KeyType: HASH
    StreamSpecification:
      StreamViewType: NEW_AND_OLD_IMAGES
```

When you add a DynamoDB table using Infrastructure Composer, you can set your table's keys by choosing **Details** on the DynamoDB table card and editing the key values. Infrastructure Composer also sets default values for a number of other properties including `BillingMode` and `StreamViewType`.

To learn more about these properties and other properties you can add to your AWS SAM template, see [AWS::DynamoDB::Table](#) in the *CloudFormation User Guide*.

- A new IAM policy that gives your function permission to perform CRUD operations on the DynamoDB table you added.

```
Policies:
```

```
...
- DynamoDBCrudPolicy:
  TableName: !Ref LambdaIaCTable
```

The complete final AWS SAM template should look like the following.

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: An AWS Serverless Specification template describing your function.
Resources:
  LambdaIaCDemo:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: .
      Description: ''
      MemorySize: 128
      Timeout: 3
      Handler: lambda_function.lambda_handler
      Runtime: python3.11
      Architectures:
        - x86_64
      EventInvokeConfig:
        MaximumEventAgeInSeconds: 21600
        MaximumRetryAttempts: 2
      EphemeralStorage:
        Size: 512
      RuntimeManagementConfig:
        UpdateRuntimeOn: Auto
      SnapStart:
        ApplyOn: None
      PackageType: Zip
      Policies:
        - Statement:
            - Effect: Allow
              Action:
                - logs:CreateLogGroup
              Resource: arn:aws:logs:us-east-1:594035263019:*
            - Effect: Allow
              Action:
                - logs:CreateLogStream
                - logs:PutLogEvents
              Resource:
```

```

- arn:aws:logs:us-east-1:594035263019:log-group:/aws/lambda/
LambdaIaCDemo:*
  - DynamoDBCrudPolicy:
      TableName: !Ref LambdaIaCTable
  Events:
    LambdaIaCQueue:
      Type: SQS
      Properties:
        Queue: !GetAtt LambdaIaCQueue.Arn
        BatchSize: 1
  Environment:
    Variables:
      LAMBDAIACTABLE_TABLE_NAME: !Ref LambdaIaCTable
      LAMBDAIACTABLE_TABLE_ARN: !GetAtt LambdaIaCTable.Arn
LambdaIaCQueue:
  Type: AWS::SQS::Queue
  Properties:
    MessageRetentionPeriod: 345600
LambdaIaCTable:
  Type: AWS::DynamoDB::Table
  Properties:
    AttributeDefinitions:
      - AttributeName: id
        AttributeType: S
    BillingMode: PAY_PER_REQUEST
    KeySchema:
      - AttributeName: id
        KeyType: HASH
    StreamSpecification:
      StreamViewType: NEW_AND_OLD_IMAGES

```

Deploy your serverless application using AWS SAM (optional)

If you want to use AWS SAM to deploy a serverless application using the template you just created in Infrastructure Composer, you first need to install the AWS SAM CLI. To do this, follow the instructions in [Installing the AWS SAM CLI](#).

Before you deploy your application, you also need to update the function code that Infrastructure Composer saved along with your template. At the moment, the `lambda_function.py` file that Infrastructure Composer saved contains only the basic 'Hello world' code that Lambda provided when you created the function.

To update your function code, copy the following code and paste it into the `lambda_function.py` file Infrastructure Composer saved to your local build machine. You specified the directory for Infrastructure Composer to save this file to when you activated Local Sync mode.

This code accepts a key value pair in a message from the Amazon SQS queue you created in Infrastructure Composer. If both the key and value are strings, the code then uses them to write an item to the DynamoDB table defined in your template.

Updated Python function code

```
import boto3
import os
import json

# define the DynamoDB table that Lambda will connect to
tablename = os.environ['LAMBDAIACTABLE_TABLE_NAME']

# create the DynamoDB resource
dynamo = boto3.client('dynamodb')

def lambda_handler(event, context):
    # get the message out of the SQS event
    message = event['Records'][0]['body']
    data = json.loads(message)
    # write event data to DDB table
    if check_message_format(data):
        key = next(iter(data))
        value = data[key]
        dynamo.put_item(
            TableName=tablename,
            Item={
                'id': {'S': key},
                'Value': {'S': value}
            }
        )
    else:
        raise ValueError("Input data not in the correct format")

# check that the event object contains a single key value
# pair that can be written to the database
def check_message_format(message):
    if len(message) != 1:
```

```
        return False

    key, value = next(iter(message.items()))

    if not (isinstance(key, str) and isinstance(value, str)):
        return False

    else:
        return True
```

To deploy your serverless application

To deploy your application using the AWS SAM CLI, carry out the following steps. For your function to build and deploy correctly, Python version 3.11 must be installed on your build machine and on your PATH.

1. Run the following command from the directory in which Infrastructure Composer saved your `template.yaml` and `lambda_function.py` files.

```
sam build
```

This command gathers the build artifacts for your application and places them in the proper format and location to deploy them.

2. To deploy your application and create the Lambda, Amazon SQS, and DynamoDB resources specified in your AWS SAM template, run the following command.

```
sam deploy --guided
```

Using the `--guided` flag means that AWS SAM will show you prompts to guide you through the deployment process. For this deployment, accept the default options by pressing Enter.

During the deployment process, AWS SAM creates the following resources in your AWS account:

- An CloudFormation [stack](#) named `sam-app`
- A Lambda function with the name format `sam-app-LambdaIaCDemo-99VXPpYQVv1M`
- An Amazon SQS queue with the name format `sam-app-LambdaIaCQueue-xL87VeKsGiIo`
- A DynamoDB table with the name format `sam-app-LambdaIaCTable-CN0S66C0VLNV`

AWS SAM also creates the necessary IAM roles and policies so that your Lambda function can read messages from the Amazon SQS queue and perform CRUD operations on the DynamoDB table.

Testing your deployed application (optional)

To confirm that your serverless application deployed correctly, send a message to your Amazon SQS queue containing a key value pair and check that Lambda writes an item into your DynamoDB table using these values.

To test your serverless application

1. Open the [Queues](#) page of the Amazon SQS console and select the queue that AWS SAM created from your template. The name has the format `sam-app-LambdaIaCQueue-xL87VeKsGiIo`.
2. Choose **Send and receive messages** and paste the following JSON into the **Message body** in the **Send message** section.

```
{
  "myKey": "myValue"
}
```

3. Choose **Send message**.

Sending your message to the queue causes Lambda to invoke your function through the event source mapping defined in your AWS SAM template. To confirm that Lambda has invoked your function as expected, confirm that an item has been added to your DynamoDB table.

4. Open the [Tables](#) page of the DynamoDB console and select your table. The name has the format `sam-app-LambdaIaCTable-CN0S66C0VLNV`.
5. Choose **Explore table items**. In the **Items returned** pane, you should see an item with the **id** `myKey` and the **Value** `myValue`.

Deploying Lambda functions with AWS CDK

The AWS Cloud Development Kit (AWS CDK) is an infrastructure as code (IaC) framework that you can use to define AWS cloud infrastructure by using a programming language of your choosing. To define your own cloud infrastructure, you first write an app (in one of the CDK's supported languages) that contains one or more stacks. Then, you synthesize it to a CloudFormation

template and deploy your resources to your AWS account. Follow the steps in this topic to deploy a Lambda function that returns an event from an Amazon API Gateway endpoint.

The AWS Construct Library, included with the CDK, provides modules that you can use to model the resources that AWS services provide. For popular services, the library provides curated constructs with smart defaults and best practices. You can use the [aws_lambda](#) module to define your function and supporting resources with just a few lines of code.

Prerequisites

Before starting this tutorial, install the AWS CDK by running the following command.

```
npm install -g aws-cdk
```

Step 1: Set up your AWS CDK project

Create a directory for your new AWS CDK app and initialize the project.

JavaScript

```
mkdir hello-lambda
cd hello-lambda
cdk init --language javascript
```

TypeScript

```
mkdir hello-lambda
cd hello-lambda
cdk init --language typescript
```

Python

```
mkdir hello-lambda
cd hello-lambda
cdk init --language python
```

After the project starts, activate the project's virtual environment and install the baseline dependencies for AWS CDK.

```
source .venv/bin/activate
```

```
python -m pip install -r requirements.txt
```

Java

```
mkdir hello-lambda  
cd hello-lambda  
cdk init --language java
```

Import this Maven project to your Java integrated development environment (IDE). For example, in Eclipse, choose **File, Import, Maven, Existing Maven Projects**.

C#

```
mkdir hello-lambda  
cd hello-lambda  
cdk init --language csharp
```

Note

The AWS CDK application template uses the name of the project directory to generate names for source files and classes. In this example, the directory is named `hello-lambda`. If you use a different project directory name, your app won't match these instructions.

AWS CDK v2 includes stable constructs for all AWS services in a single package that's called `aws-cdk-lib`. This package is installed as a dependency when you initialize the project. When working with certain programming languages, the package is installed when you build the project for the first time.

Step 2: Define the AWS CDK stack

A CDK *stack* is a collection of one or more constructs, which define AWS resources. Each CDK stack represents an CloudFormation stack in your CDK app.

To define your CDK stack, follow the instructions for your preferred programming language. This stack defines the following:

- The function's logical name: `MyFunction`

- The location of the function code, specified in the code property. For more information, see [Handler code](#) in the *AWS Cloud Development Kit (AWS CDK) API Reference*.
- The REST API's logical name: `HelloApi`
- The API Gateway endpoint's logical name: `ApiGwEndpoint`

Note that all of the CDK stacks in this tutorial use the Node.js [runtime](#) for the Lambda function. You can use different programming languages for the CDK stack and the Lambda function to leverage the strengths of each language. For example, you can use TypeScript for the CDK stack to leverage the benefits of static typing for your infrastructure code. You can use JavaScript for the Lambda function to take advantage of the flexibility and rapid development of a dynamically typed language.

JavaScript

Open the `lib/hello-lambda-stack.js` file and replace the contents with the following.

```
const { Stack } = require('aws-cdk-lib');
const lambda = require('aws-cdk-lib/aws-lambda');
const apigw = require('aws-cdk-lib/aws-apigateway');

class HelloLambdaStack extends Stack {
  /**
   * @param {Construct} scope
   * @param {string} id
   * @param {StackProps=} props
   */
  constructor(scope, id, props) {
    super(scope, id, props);
    const fn = new lambda.Function(this, 'MyFunction', {
      code: lambda.Code.fromAsset('lib/lambda-handler'),
      runtime: lambda.Runtime.NODEJS_LATEST,
      handler: 'index.handler'
    });

    const endpoint = new apigw.LambdaRestApi(this, 'MyEndpoint', {
      handler: fn,
      restApiName: "HelloApi"
    });
  }
}
```

```
}

module.exports = { HelloLambdaStack }
```

TypeScript

Open the `lib/hello-lambda-stack.ts` file and replace the contents with the following.

```
import * as cdk from 'aws-cdk-lib';
import { Construct } from 'constructs';
import * as apigw from "aws-cdk-lib/aws-apigateway";
import * as lambda from "aws-cdk-lib/aws-lambda";
import * as path from 'node:path';

export class HelloLambdaStack extends cdk.Stack {
  constructor(scope: Construct, id: string, props?: cdk.StackProps) {
    super(scope, id, props);
    const fn = new lambda.Function(this, 'MyFunction', {
      runtime: lambda.Runtime.NODEJS_LATEST,
      handler: 'index.handler',
      code: lambda.Code.fromAsset(path.join(__dirname, 'lambda-handler')),
    });

    const endpoint = new apigw.LambdaRestApi(this, `ApiGwEndpoint`, {
      handler: fn,
      restApiName: `HelloApi`,
    });
  }
}
```

Python

Open the `/hello-lambda/hello_lambda/hello_lambda_stack.py` file and replace the contents with the following.

```
from aws_cdk import (
    Stack,
    aws_apigateway as apigw,
    aws_lambda as _lambda
)
from constructs import Construct
```

```
class HelloLambdaStack(Stack):

    def __init__(self, scope: Construct, construct_id: str, **kwargs) -> None:
        super().__init__(scope, construct_id, **kwargs)

        fn = _lambda.Function(
            self,
            "MyFunction",
            runtime=_lambda.Runtime.NODEJS_LATEST,
            handler="index.handler",
            code=_lambda.Code.from_asset("lib/lambda-handler")
        )

        endpoint = apigw.LambdaRestApi(
            self,
            "ApiGwEndpoint",
            handler=fn,
            rest_api_name="HelloApi"
        )
```

Java

Open the `/hello-lambda/src/main/java/com/myorg/HelloLambdaStack.java` file and replace the contents with the following.

```
package com.myorg;

import software.constructs.Construct;
import software.amazon.awscdk.Stack;
import software.amazon.awscdk.StackProps;
import software.amazon.awscdk.services.apigateway.LambdaRestApi;
import software.amazon.awscdk.services.lambda.Function;

public class HelloLambdaStack extends Stack {
    public HelloLambdaStack(final Construct scope, final String id) {
        this(scope, id, null);
    }

    public HelloLambdaStack(final Construct scope, final String id, final StackProps props) {
        super(scope, id, props);

        Function hello = Function.Builder.create(this, "MyFunction")
```

```

.runtime(software.amazon.awscdk.services.lambda.Runtime.NODEJS_LATEST)

.code(software.amazon.awscdk.services.lambda.Code.fromAsset("lib/lambda-handler"))
    .handler("index.handler")
    .build();

    LambdaRestApi api = LambdaRestApi.Builder.create(this, "ApiGwEndpoint")
        .restApiName("HelloApi")
        .handler(hello)
        .build();

    }
}

```

C#

Open the `src/HelloLambda/HelloLambdaStack.cs` file and replace the contents with the following.

```

using Amazon.CDK;
using Amazon.CDK.AWS.APIGateway;
using Amazon.CDK.AWS.Lambda;
using Constructs;

namespace HelloLambda
{
    public class HelloLambdaStack : Stack
    {
        internal HelloLambdaStack(Construct scope, string id, IStackProps props =
null) : base(scope, id, props)
        {
            var fn = new Function(this, "MyFunction", new FunctionProps
            {
                Runtime = Runtime.NODEJS_LATEST,
                Code = Code.FromAsset("lib/lambda-handler"),
                Handler = "index.handler"
            });

            var api = new LambdaRestApi(this, "ApiGwEndpoint", new
LambdaRestApiProps
            {
                Handler = fn
            });
        }
    }
}

```

```
    });  
  }  
}  
}
```

Step 3: Create the Lambda function code

1. From the root of your project (hello-lambda), create the `/lib/lambda-handler` directory for the Lambda function code. This directory is specified in the code property of your AWS CDK stack.
2. Create a new file called `index.js` in the `/lib/lambda-handler` directory. Paste the following code into the file. The function extracts specific properties from the API request and returns them as a JSON response.

```
exports.handler = async (event) => {  
  // Extract specific properties from the event object  
  const { resource, path, httpMethod, headers, queryStringParameters, body } =  
    event;  
  const response = {  
    resource,  
    path,  
    httpMethod,  
    headers,  
    queryStringParameters,  
    body,  
  };  
  return {  
    body: JSON.stringify(response, null, 2),  
    statusCode: 200,  
  };  
};
```

Step 4: Deploy the AWS CDK stack

1. From the root of your project, run the [cdk synth](#) command:

```
cdk synth
```

This command synthesizes an AWS CloudFormation template from your CDK stack. The template is an approximately 400-line YAML file, similar to the following.

Note

If you get the following error, make sure that you are in the root of your project directory.

```
--app is required either in command-line, in cdk.json or in ~/.cdk.json
```

Example CloudFormation template

```
Resources:
  MyFunctionServiceRole3C357FF2:
    Type: AWS::IAM::Role
    Properties:
      AssumeRolePolicyDocument:
        Statement:
          - Action: sts:AssumeRole
            Effect: Allow
            Principal:
              Service: lambda.amazonaws.com
        Version: "2012-10-17"
      ManagedPolicyArns:
        - Fn::Join:
            - ""
            - - "arn:"
              - Ref: AWS::Partition
              - :iam::aws:policy/service-role/AWSLambdaBasicExecutionRole
      Metadata:
        aws:cdk:path: HelloLambdaStack/MyFunction/ServiceRole/Resource
  MyFunction1BAA52E7:
    Type: AWS::Lambda::Function
    Properties:
      Code:
        S3Bucket:
          Fn::Sub: cdk-hnb659fds-assets-${AWS::AccountId}-${AWS::Region}
        S3Key:
          ab111111cd32708dc4b83e81a21c296d607ff2cdef00f1d7f48338782f9213901.zip
```

```
Handler: index.handler
Role:
  Fn::GetAtt:
    - MyFunctionServiceRole3C357FF2
    - Arn
Runtime: nodejs24.x
...
```

2. Run the `cdk deploy` command:

```
cdk deploy
```

Wait while your resources are created. The final output includes the URL for your API Gateway endpoint. Example:

```
Outputs:
HelloLambdaStack.ApiGwEndpoint77F417B1 = https://abcd1234.execute-api.us-east-1.amazonaws.com/prod/
```

Step 5: Test the function

To invoke the Lambda function, copy the API Gateway endpoint and paste it into a web browser or run a `curl` command:

```
curl -s https://abcd1234.execute-api.us-east-1.amazonaws.com/prod/
```

The response is a JSON representation of selected properties from the original event object, which contains information about the request made to the API Gateway endpoint. Example:

```
{
  "resource": "/",
  "path": "/",
  "httpMethod": "GET",
  "headers": {
    "Accept": "text/html,application/xhtml+xml,application/xml;q=0.9,image/avif,image/webp,image/apng,*/*;q=0.8,application/signed-exchange;v=b3;q=0.7",
    "Accept-Encoding": "gzip, deflate, br, zstd",
    "Accept-Language": "en-US,en;q=0.9",
    "CloudFront-Forwarded-Proto": "https",
    "CloudFront-Is-Desktop-Viewer": "true",
```

```
"CloudFront-Is-Mobile-Viewer": "false",  
"CloudFront-Is-SmartTV-Viewer": "false",  
"CloudFront-Is-Tablet-Viewer": "false",  
"CloudFront-Viewer-ASN": "16509",  
"CloudFront-Viewer-Country": "US",  
"Host": "abcd1234.execute-api.us-east-1.amazonaws.com",  
...
```

Step 6: Clean up your resources

The API Gateway endpoint is publicly accessible. To prevent unexpected charges, run the [cdk destroy](#) command to delete the stack and all associated resources.

```
cdk destroy
```

Powertools for AWS Lambda

Powertools for AWS Lambda (also referred to as Powertools for AWS) provides utility functions, decorators, and middleware that handle common Lambda tasks like structured logging, tracing, metrics collection, and input validation. Use Powertools for AWS Lambda to implement serverless best practices and accelerate development across multiple Lambda functions. Doing this simplifies common development tasks in your Lambda functions.

Key benefits of Powertools for AWS

While Lambda development is possible without Powertools for AWS, using it offers several advantages:

- Built-in observability: Structured logging, tracing, and custom metrics
- Secrets management: Parameter retrieval, secrets handling, and idempotency
- Progressive Enhancement: Choose the utilities that best suit your needs
- Accelerated development: Event parsing, validation, and batch processing
- Best practices: Implementation of AWS Well-Architected serverless patterns

Integrating Powertools with AWS

Powertools for AWS helps you build production-ready serverless applications with less custom code. Available in Python, TypeScript/Node.js, .NET, and Java, Powertools for AWS can be included through Lambda Layers, or using the language package manager. Each language implementation provides core features like structured logging, tracing, metrics collection, and event handling, while maintaining idioms natural to each programming language. These implementations are complemented by specialized components for AWS service integration, supporting parameter retrieval, batch processing, and API handling, along with best practices like correlation ID propagation, error handling, and idempotency patterns. Together, these features enable developers to build robust, maintainable serverless applications while reducing custom code overhead.

Managing Lambda workflows and events

When building serverless applications with Lambda, you often need ways to orchestrate function execution and handle events. AWS provides several approaches for coordinating Lambda functions:

- [Lambda durable functions](#) for code-first workflow orchestration within Lambda
- AWS Step Functions for visual workflow orchestration across multiple services
- Amazon EventBridge Scheduler and Amazon EventBridge for event-driven architectures and scheduling

You can also integrate these approaches together. For example, you might use EventBridge Scheduler to trigger durable functions or Step Functions workflows when specific events occur, or configure workflows to publish events to EventBridge Scheduler at defined execution points. The following topics in this section provide more information on how you can use these orchestration options.

Code-first orchestration with durable functions

Lambda durable functions provide a code-first approach to workflow orchestration, allowing you to build stateful, long-running workflows directly within your Lambda functions. Unlike external orchestration services, durable functions keep your workflow logic in code, making it easier to version, test, and maintain alongside your business logic.

Durable functions are ideal when you need:

- **Use standard programming languages:** Define workflows using familiar programming languages like JavaScript and Python

- **Long-running processes:** Execute workflows that can run for up to one year, far beyond the 15-minute limit of standard Lambda functions
- **Simplified development:** Keep workflow logic and business logic in the same codebase for easier maintenance and testing
- **Cost-effective waiting:** Pause execution during wait states without consuming compute resources
- **Built-in state management:** Automatic checkpointing and state persistence without external storage configuration

For help choosing between durable functions and Step Functions, see [Durable functions or Step Functions](#).

For more information on durable functions, see [Lambda durable functions](#).

Orchestrating workflows with Step Functions

AWS Step Functions is a workflow orchestration service that helps you coordinate multiple Lambda functions and other AWS services into structured workflows. These workflows can maintain state, handle errors with sophisticated retry mechanisms, and process data at scale.

Step Functions offers two types of workflows to meet different orchestration needs:

Standard workflows

Ideal for long-running, auditable workflows that require exactly-once execution semantics. Standard workflows can run for up to one year, provide detailed execution history, and support visual debugging. They are suitable for processes like order fulfillment, data processing pipelines, or multi-step analytics jobs.

Express workflows

Designed for high-event-rate, short-duration workloads with at-least-once execution semantics. Express workflows can run for up to five minutes and are ideal for high-volume event processing, streaming data transformations, or IoT data ingestion scenarios. They offer higher throughput and potentially lower cost compared to Standard workflows.

Note

For more information on Step Functions workflow types, see [Choosing workflow type in Step Functions](#).

Within these workflows, Step Functions provides two types of Map states for parallel processing:

Inline Map

Processes items from a JSON array within the execution history of the parent workflow. Inline Map supports up to 40 concurrent iterations and is suitable for smaller datasets or when you need to keep all processing within a single execution. For more information, see [Using Map state in Inline mode](#).

Distributed Map

Enables processing of large-scale parallel workloads by iterating over datasets that exceed 256 KiB or require more than 40 concurrent iterations. With support for up to 10,000 parallel child workflow executions, Distributed Map excels at processing semi-structured data stored in Amazon S3, such as JSON or CSV files, making it ideal for batch processing and ETL operations. For more information, see [Using Map state in Distributed mode](#).

By combining these workflow types and Map states, Step Functions provides a flexible and powerful toolset for orchestrating complex serverless applications, from small-scale operations to large-scale data processing pipelines.

To get started with using Lambda with Step Functions, see [Orchestrating Lambda functions with Step Functions](#).

Managing events with EventBridge and EventBridge Scheduler

Amazon EventBridge is an event bus service that helps you build event-driven architectures. It routes events between AWS services, integrated applications, and software as a service (SaaS) applications. EventBridge Scheduler is a serverless scheduler that enables you to create, run, and manage tasks from one central service, allowing you to invoke Lambda functions on a schedule using cron and rate expressions, or configure one-time invocations.

Amazon EventBridge and EventBridge Scheduler help you build event-driven architectures with Lambda. EventBridge routes events between AWS services, integrated applications, and SaaS

applications, while EventBridge Scheduler provides specific scheduling capabilities for invoking Lambda functions on a recurring or one-time basis.

These services provide several key capabilities for working with Lambda functions:

- Create rules that match and route events to Lambda functions using EventBridge
- Set up recurring function invocations using cron and rate expressions with EventBridge Scheduler
- Configure one-time function invocations at specific dates and times
- Define flexible time windows and retry policies for scheduled invocations

For more information, see [Invoke a Lambda function on a schedule](#).

Lambda durable functions

Lambda durable functions enable you to build resilient multi-step applications and AI workflows that can execute for up to one year while maintaining reliable progress despite interruptions. When a durable function runs, this complete lifecycle is called a durable execution, which uses checkpoints to track progress and automatically recover from failures through replay, re-executing from the beginning while skipping completed work.

Within each function, you use durable operations as fundamental building blocks. Steps execute business logic with built-in retries and progress tracking, while waits suspend execution without incurring compute charges, making them ideal for long-running processes like human-in-the-loop workflows or polling external dependencies. Whether you're processing orders, coordinating microservices, or orchestrating agentic AI applications, durable functions maintain state automatically and recover from failures while you write code in familiar programming languages.

Key benefits

Write resilient code naturally: With familiar programming constructs, you write code that handles failures automatically. Built-in checkpointing, transparent retries, and automatic recovery mean your business logic stays clean and focused.

Pay only for what you use: During wait operations, your function suspends without incurring compute charges. For long-running workflows that wait hours or days, you pay only for actual processing time, not idle waiting.

Operational simplicity: With Lambda's serverless model, you get automatic scaling, including scale-to-zero, without managing infrastructure. Durable functions handle state management, retry logic, and failure recovery automatically, reducing operational overhead.

When to use durable functions

Short-lived coordination: Coordinate payments, inventory, and shipping across multiple services with automatic rollback on failures. Process orders through validation, payment authorization, inventory allocation, and fulfillment with guaranteed completion.

Process payments with confidence: Build resilient payment flows that maintain transaction state through failures and handle retries automatically. Coordinate multi-step authorization, fraud checks, and settlement across payment providers with full auditability across steps.

Build reliable AI workflows: Create multi-step AI workflows that chain model calls, incorporate human feedback, and handle long-running tasks deterministically during failures. Automatically resume after suspension, and only pay for active execution time.

Orchestrate complex order fulfillment: Coordinate order processing across inventory, payment, shipping, and notification systems with built-in resilience. Automatically handle partial failures, preserve order state despite interruptions, and efficiently wait for external events without consuming compute resources.

Automate multi-step business workflows: Build reliable workflows for employee onboarding, loan approvals, and compliance processes that span days or weeks. Maintain workflow state across human approvals, system integrations, and scheduled tasks while providing full visibility into process status and history.

How durable functions compare to Step Functions

Both, durable functions and Step Functions, provide workflow orchestration with automatic state management. The key differences are where they run and how you define workflows:

- **Durable functions:** Run within Lambda, use standard programming languages, managed within Lambda environment
- **Step Functions:** Standalone service, graph-based DSL or visual designer, fully managed with zero maintenance

Durable functions are ideal for application development in Lambda where workflows are tightly coupled with business logic. Step Functions excels at workflow orchestration across AWS services where you need visual design, native integrations to 220+ services, and zero-maintenance infrastructure.

For a detailed comparison, see [Durable functions or Step Functions](#).

How it works

Under the hood, durable functions are regular Lambda functions using a checkpoint/replay mechanism to track progress and support long-running operations through user-defined suspension points, commonly referred to as durable execution. When a durable function resumes from a wait point or interruption like retries, the system performs replay. During replay, your code

runs from the beginning but skips over completed checkpoints, using stored results instead of re-executing completed operations. This replay mechanism ensures consistency while enabling long-running executions.

After your function resumes from a pause or interruption, the system performs replay. During replay, your code runs from the beginning but skips over completed checkpoints, using stored results instead of re-executing completed operations. This replay mechanism ensures consistency while enabling long-running executions.

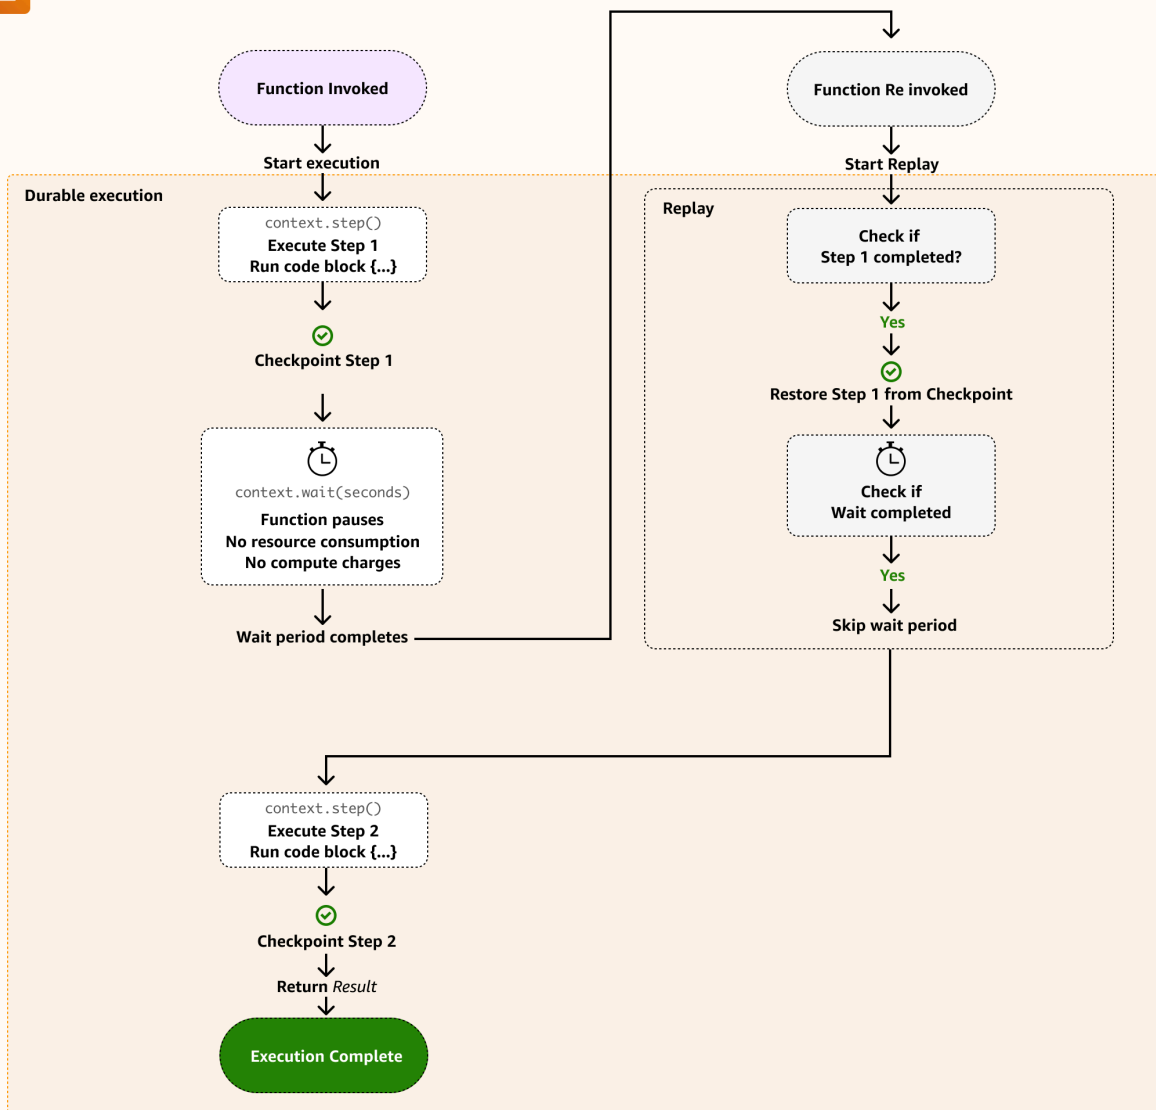

To harness this checkpoint-and-replay mechanism in your applications, Lambda provides a durable execution SDK. The SDK abstracts away the complexity of managing checkpoints and replay, exposing simple primitives called durable operations that you use in your code. The SDK is available for JavaScript, TypeScript, and Python, integrating seamlessly with your existing Lambda development workflow.

With the SDK, you wrap your Lambda event handler, which then provides a `DurableContext` alongside your event. This context gives you access to durable operations like steps and waits. You write your function logic as normal sequential code, but instead of calling services directly, you wrap those calls in steps for automatic checkpointing and retries. When you need to pause execution, you add waits that suspend your function without incurring charges. The SDK handles all the complexity of state management and replay behind the scenes, so your code remains clean and readable.

- [Follow best practices](#)

Basic concepts

Lambda provides durable execution SDKs for JavaScript, TypeScript, and Python. These SDKs are the foundation for building durable functions, providing the primitives you need to checkpoint progress, handle retries, and manage execution flow. For complete SDK documentation and examples, see the [JavaScript/TypeScript SDK](#) and [Python SDK](#) on GitHub.

Durable execution

A **durable execution** represents the complete lifecycle of a Lambda durable function, using a checkpoint and replay mechanism to track business logic progress, suspend execution, and recover from failures. When functions resume after suspension or interruptions, previously completed checkpoints are replayed and the function continues execution.

The lifecycle may include multiple invocations of a Lambda function to complete the execution, particularly after suspensions or failure recovery. This approach enables your function to run for extended periods (up to one year) while maintaining reliable progress despite interruptions.

How replay works

Lambda keeps a running log of all durable operations (steps, waits, and other operations) as your function executes. When your function needs to pause or encounters an interruption, Lambda saves this checkpoint log and stops the execution. When it's time to resume, Lambda invokes your function again from the beginning and replays the checkpoint log, substituting stored values for completed operations. This means your code runs again, but previously completed steps don't re-execute. Their stored results are used instead.

This replay mechanism is fundamental to understanding durable functions. Your code must be deterministic during replay, meaning it produces the same results given the same inputs. Avoid operations with side effects (like generating random numbers or getting the current time) outside of steps, as these can produce different values during replay and cause non-deterministic behavior.

DurableContext

DurableContext is the context object your durable function receives. It provides methods for durable operations like steps and waits that create checkpoints and manage execution flow.

Your durable function receives a `DurableContext` instead of the default Lambda context:

TypeScript

```
import {
  DurableContext,
  withDurableExecution,
} from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const result = await context.step(async () => {
      return "step completed";
    });
    return result;
  },
);
```

Python

```
from aws_durable_execution_sdk_python import (
    DurableContext,
    durable_execution,
    durable_step,
)

@durable_step
def my_step(step_context, data):
    # Your business logic
    return result

@durable_execution
def handler(event, context: DurableContext):
    result = context.step(my_step(event["data"]))
    return result
```

The Python SDK for durable functions uses synchronous methods and doesn't support `await`. The TypeScript SDK uses `async/await`.

Steps

Steps runs business logic with built-in retries and automatic checkpointing. Each step saves its result, ensuring your function can resume from any completed step after interruptions.

TypeScript

```
// Each step is automatically checkpointed
const order = await context.step(async () => processOrder(event));
const payment = await context.step(async () => processPayment(order));
const result = await context.step(async () => completeOrder(payment));
```

Python

```
# Each step is automatically checkpointed
order = context.step(lambda: process_order(event))
payment = context.step(lambda: process_payment(order))
result = context.step(lambda: complete_order(payment))
```

Wait States

Wait states are planned pauses where your function stops running (and stops charging) until it's time to continue. Use them to wait for time periods, external callbacks, or specific conditions.

TypeScript

```
// Wait for 1 hour without consuming resources
await context.wait({ seconds:3600 });

// Wait for external callback
const approval = await context.waitForCallback(
  async (callbackId) => sendApprovalRequest(callbackId)
);
```

Python

```
# Wait for 1 hour without consuming resources
```

```
context.wait(3600)

# Wait for external callback
approval = context.wait_for_callback(
    lambda callback_id: send_approval_request(callback_id)
)
```

When your function encounters a wait or needs to pause, Lambda saves the checkpoint log and stops the execution. When it's time to resume, Lambda invokes your function again and replays the checkpoint log, substituting stored values for completed operations.

For more complex workflows, durable Lambda functions also come with advanced operations like `parallel()` for concurrent execution, `map()` for processing arrays, `runInChildContext()` for nested operations, and `waitForCondition()` for polling. See [Examples](#) for detailed examples and guidance on when to use each operation.

Invoking other functions

Invoke allows a durable function to call other Lambda functions and wait for their results. The calling function suspends while the invoked function executes, creating a checkpoint that preserves the result. This enables you to build modular workflows where specialized functions handle specific tasks.

Use `context.invoke()` to call other functions from within your durable function. The invocation is checkpointed, so if your function is interrupted after the invoked function completes, it resumes with the stored result without re-invoking the function.

TypeScript

```
// Invoke another function and wait for result
const customerData = await context.invoke(
    'validate-customer',
    'arn:aws:lambda:us-east-1:123456789012:function:customer-service:1',
    { customerId: event.customerId }
);

// Use the result in subsequent steps
const order = await context.step(async () => {
    return processOrder(customerData);
});
```

Python

```
# Invoke another function and wait for result
customer_data = context.invoke(
    'arn:aws:lambda:us-east-1:123456789012:function:customer-service:1',
    {'customerId': event['customerId']],
    name='validate-customer'
)

# Use the result in subsequent steps
order = context.step(
    lambda: process_order(customer_data),
    name='process-order'
)
```

The invoked function can be either a durable or standard Lambda function. If you invoke a durable function, the calling function waits for the complete durable execution to finish. This pattern is common in microservices architectures where each function handles a specific domain, allowing you to compose complex workflows from specialized, reusable functions.

Note

Cross-account invocations are not supported. The invoked function must be in the same AWS account as the calling function.

Durable function configuration

Durable functions have specific configuration settings that control execution behavior and data retention. These settings are separate from standard Lambda function configuration and apply to the entire durable execution lifecycle.

The **DurableConfig** object defines the configuration for durable functions:

```
{
  "ExecutionTimeout": Integer,
  "RetentionPeriodInDays": Integer
}
```

Execution timeout

The **execution timeout** controls how long a durable execution can run from start to completion. This is different from the Lambda function timeout, which controls how long a single function invocation can run.

A durable execution can span multiple Lambda function invocations as it progresses through checkpoints, waits, and replays. The execution timeout applies to the total elapsed time of the durable execution, not to individual function invocations.

Understanding the difference

The Lambda function timeout (maximum 15 minutes) limits each individual invocation of your function. The durable execution timeout (maximum 1 year) limits the total time from when the execution starts until it completes, fails, or times out. During this period, your function may be invoked multiple times as it processes steps, waits, and recovers from failures.

For example, if you set a durable execution timeout of 24 hours and a Lambda function timeout of 5 minutes:

- Each function invocation must complete within 5 minutes
- The entire durable execution can run for up to 24 hours
- Your function can be invoked many times during those 24 hours
- Wait operations don't count against the Lambda function timeout but do count against the execution timeout

You can configure the execution timeout when creating a durable function using the Lambda console, AWS CLI, or AWS SAM. In the Lambda console, choose your function, then Configuration, Durable execution. Set the Execution timeout value in seconds (default: 86400 seconds / 24 hours, minimum: 60 seconds, maximum: 31536000 seconds / 1 year).

Note

The execution timeout and Lambda function timeout are different settings. The Lambda function timeout controls how long each individual invocation can run (maximum 15 minutes). The execution timeout controls the total elapsed time for the entire durable execution (maximum 1 year).

Retention period

The **retention period** controls how long Lambda retains execution history and checkpoint data after a durable execution completes. This data includes step results, execution state, and the complete checkpoint log.

After the retention period expires, Lambda deletes the execution history and checkpoint data. You can no longer retrieve execution details or replay the execution. The retention period starts when the execution reaches a terminal state (SUCCEEDED, FAILED, STOPPED, or TIMED_OUT).

You can configure the retention period when creating a durable function using the Lambda console, AWS CLI, or AWS SAM. In the Lambda console, choose your function, then Configuration, Durable execution. Set the Retention period value in days (default: 14 days, minimum: 1 day, maximum: 90 days).

Choose a retention period based on your compliance requirements, debugging needs, and cost considerations. Longer retention periods provide more time for debugging and auditing but increase storage costs.

See also

- [Durable functions or Step Functions](#) – Compare durable functions with Step Functions to understand when each approach is most effective.

Creating Lambda durable functions

To get started with Lambda durable functions, use the Lambda console to create a durable function. In a few minutes, you can create and deploy a durable function that uses steps and waits to demonstrate checkpoint-based execution.

As you carry out the tutorial, you'll learn fundamental durable function concepts, like how to use the `DurableContext` object, create checkpoints with steps, and pause execution with waits. You'll also learn how replay works when your function resumes after a wait.

To keep things simple, you create your function using either the Python or Node.js runtime. With these interpreted languages, you can edit function code directly in the console's built-in code editor.

Note

Durable functions currently support Python and Node.js (JavaScript/TypeScript) runtimes. For a complete list of supported runtime versions and container image options, see [Supported runtimes for durable functions](#).

Tip

To learn how to build **serverless solutions**, check out the [Serverless Developer Guide](#).

Prerequisites

Sign up for an AWS account

If you do not have an AWS account, complete the following steps to create one.

To sign up for an AWS account

1. Open <https://portal.aws.amazon.com/billing/signup>.
2. Follow the online instructions.

Part of the sign-up procedure involves receiving a phone call or text message and entering a verification code on the phone keypad.

When you sign up for an AWS account, an *AWS account root user* is created. The root user has access to all AWS services and resources in the account. As a security best practice, assign administrative access to a user, and use only the root user to perform [tasks that require root user access](#).

AWS sends you a confirmation email after the sign-up process is complete. At any time, you can view your current account activity and manage your account by going to <https://aws.amazon.com/> and choosing **My Account**.

Create a user with administrative access

After you sign up for an AWS account, secure your AWS account root user, enable AWS IAM Identity Center, and create an administrative user so that you don't use the root user for everyday tasks.

Secure your AWS account root user

1. Sign in to the [AWS Management Console](#) as the account owner by choosing **Root user** and entering your AWS account email address. On the next page, enter your password.

For help signing in by using root user, see [Signing in as the root user](#) in the *AWS Sign-In User Guide*.

2. Turn on multi-factor authentication (MFA) for your root user.

For instructions, see [Enable a virtual MFA device for your AWS account root user \(console\)](#) in the *IAM User Guide*.

Create a user with administrative access

1. Enable IAM Identity Center.

For instructions, see [Enabling AWS IAM Identity Center](#) in the *AWS IAM Identity Center User Guide*.

2. In IAM Identity Center, grant administrative access to a user.

For a tutorial about using the IAM Identity Center directory as your identity source, see [Configure user access with the default IAM Identity Center directory](#) in the *AWS IAM Identity Center User Guide*.

Sign in as the user with administrative access

- To sign in with your IAM Identity Center user, use the sign-in URL that was sent to your email address when you created the IAM Identity Center user.

For help signing in using an IAM Identity Center user, see [Signing in to the AWS access portal](#) in the *AWS Sign-In User Guide*.

Assign access to additional users

1. In IAM Identity Center, create a permission set that follows the best practice of applying least-privilege permissions.

For instructions, see [Create a permission set](#) in the *AWS IAM Identity Center User Guide*.

2. Assign users to a group, and then assign single sign-on access to the group.

For instructions, see [Add groups](#) in the *AWS IAM Identity Center User Guide*.

Create a Lambda durable function with the console

In this example, your durable function processes an order through multiple steps with automatic checkpointing. The function takes a JSON object containing an order ID, validates the order, processes payment, and confirms the order. Each step is automatically checkpointed, so if the function is interrupted, it resumes from the last completed step.

Your function also demonstrates a wait operation, pausing execution for a short period to simulate waiting for external confirmation.

To create a durable function with the console

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Select **Author from scratch**.
4. In the **Basic information** pane, for **Function name**, enter **myDurableFunction**.
5. For **Runtime**, choose either **Node.js 24** or **Python 3.14**.
6. Select **Enable durable execution**.

Lambda creates your durable function with an [execution role](#) that includes permissions for checkpoint operations (`lambda:CheckpointDurableExecutions` and `lambda:GetDurableExecutionState`).

Note

Lambda runtimes include the Durable Execution SDK, so you can test durable functions without packaging dependencies. However, we recommend including the SDK in your deployment package for production. This ensures version consistency and avoids potential runtime updates that might affect your function.

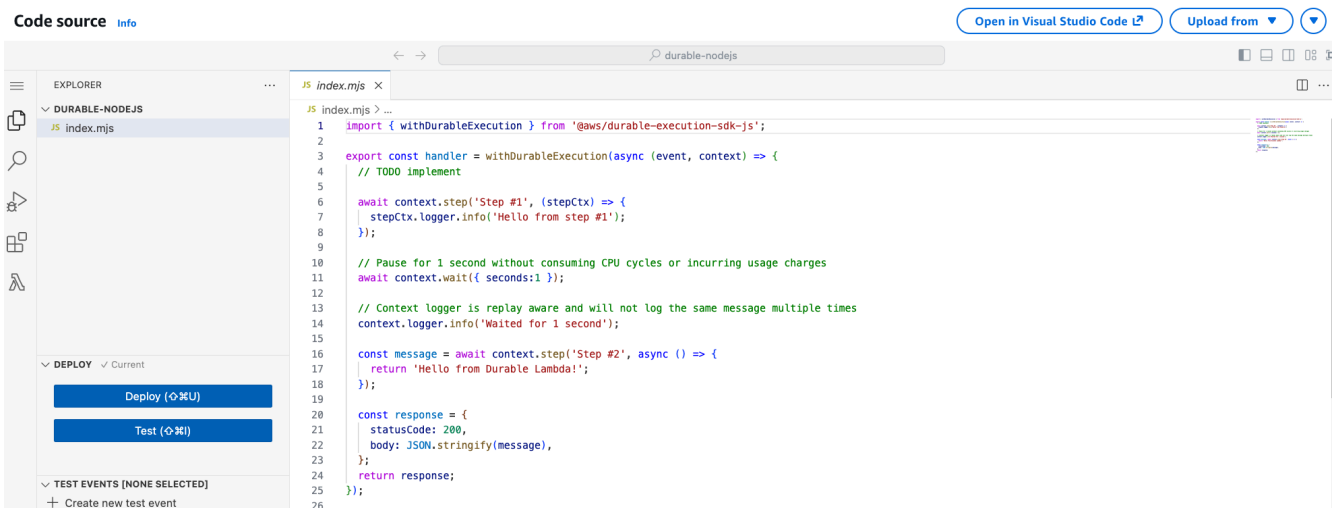

Use the console's built-in code editor to add your durable function code.

Node.js

To modify the code in the console

1. Choose the **Code** tab.

In the console's built-in code editor, you should see the function code that Lambda created. If you don't see the **index.mjs** tab in the code editor, select **index.mjs** in the file explorer as shown on the following diagram.

2. Paste the following code into the **index.mjs** tab, replacing the code that Lambda created.

```
import {
  DurableContext,
  withDurableExecution,
} from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event, context) => {
    const orderId = event.orderId;

    // Step 1: Validate order
    const validationResult = await context.step(async (stepContext) => {
      stepContext.logger.info(`Validating order ${orderId}`);
      return { orderId, status: "validated" };
    });

    // Step 2: Process payment
    const paymentResult = await context.step(async (stepContext) => {
      stepContext.logger.info(`Processing payment for order ${orderId}`);
```

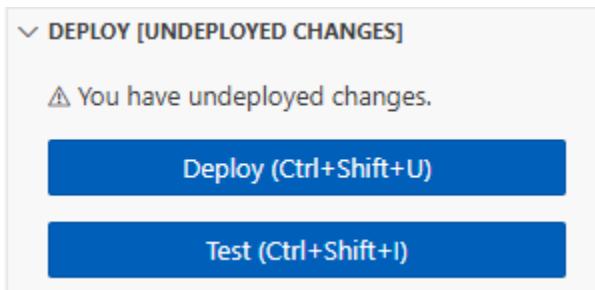

```
        return { orderId, status: "paid", amount: 99.99 };
    });

    // Wait for 10 seconds to simulate external confirmation
    await context.wait({ seconds: 10 });

    // Step 3: Confirm order
    const confirmationResult = await context.step(async (stepContext) => {
        stepContext.logger.info(`Confirming order ${orderId}`);
        return { orderId, status: "confirmed" };
    });

    return {
        orderId: orderId,
        status: "completed",
        steps: [validationResult, paymentResult, confirmationResult]
    };
}
);
```

3. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Understanding your durable function code

Before you move to the next step, let's look at the function code and understand key durable function concepts.

- The `withDurableExecution` wrapper:

Your durable function is wrapped with `withDurableExecution`. This wrapper enables durable execution by providing the `DurableContext` object and managing checkpoint operations.

- The `DurableContext` object:

Instead of the standard Lambda context, your function receives a `DurableContext`. This object provides methods for durable operations like `step()` and `wait()` that create checkpoints.

- Steps and checkpoints:

Each `context.step()` call creates a checkpoint before and after execution. If your function is interrupted, it resumes from the last completed checkpoint. The function doesn't re-execute completed steps. It uses their stored results instead.

- Wait operations:

The `context.wait()` call pauses execution without consuming compute resources. When the wait completes, Lambda invokes your function again and replays the checkpoint log, substituting stored values for completed steps.

- Replay mechanism:

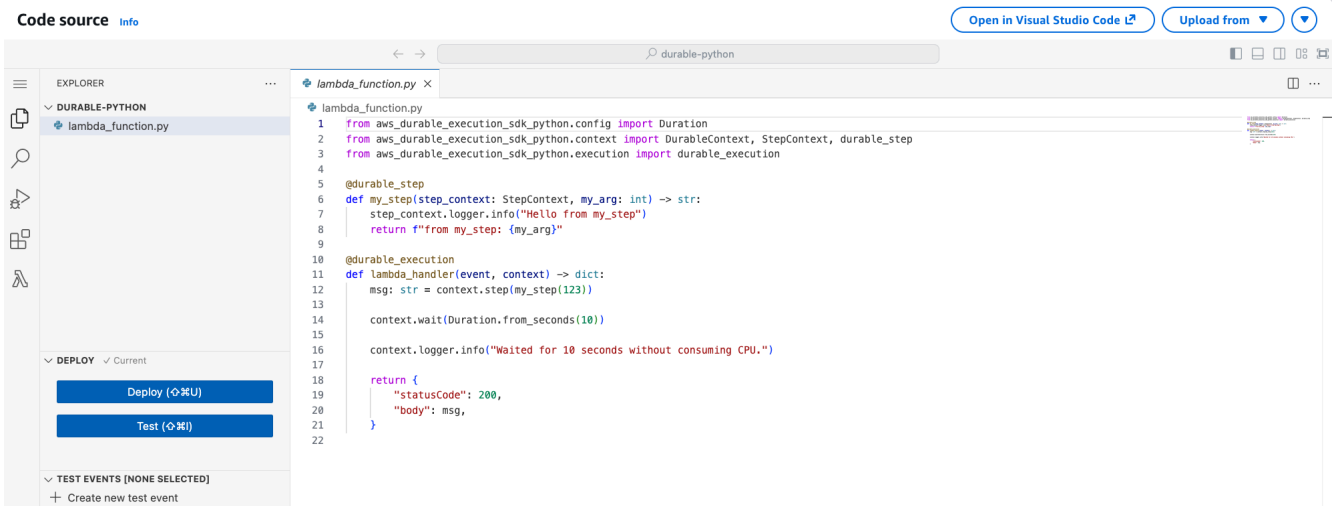

When your function resumes after a wait or interruption, Lambda runs your code from the beginning. However, completed steps don't re-execute. Lambda replays their results from the checkpoint log. This is why your code must be deterministic.

Python

To modify the code in the console

1. Choose the **Code** tab.

In the console's built-in code editor, you should see the function code that Lambda created. If you don't see the **lambda_function.py** tab in the code editor, select **lambda_function.py** in the file explorer as shown on the following diagram.

2. Paste the following code into the **lambda_function.py** tab, replacing the code that Lambda created.

```

from aws_durable_execution_sdk_python import (
    DurableContext,
    durable_execution,
    durable_step,
)
from aws_durable_execution_sdk_python.config import Duration

@durable_step
def validate_order(step_context, order_id):
    step_context.logger.info(f"Validating order {order_id}")
    return {"orderId": order_id, "status": "validated"}

@durable_step
def process_payment(step_context, order_id):
    step_context.logger.info(f"Processing payment for order {order_id}")
    return {"orderId": order_id, "status": "paid", "amount": 99.99}

@durable_step
def confirm_order(step_context, order_id):
    step_context.logger.info(f"Confirming order {order_id}")
    return {"orderId": order_id, "status": "confirmed"}

@durable_execution
def lambda_handler(event, context: DurableContext):
    order_id = event['orderId']

    # Step 1: Validate order

```

```
validation_result = context.step(validate_order(order_id))

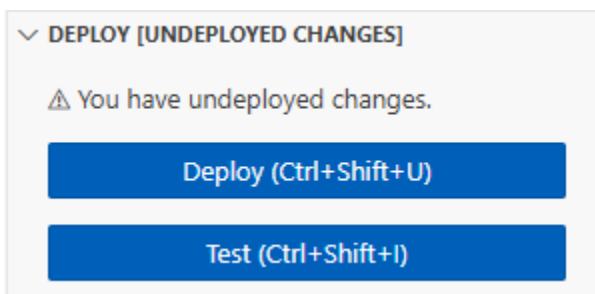

# Step 2: Process payment
payment_result = context.step(process_payment(order_id))

# Wait for 10 seconds to simulate external confirmation
context.wait(Duration.from_seconds(10))

# Step 3: Confirm order
confirmation_result = context.step(confirm_order(order_id))

return {
    "orderId": order_id,
    "status": "completed",
    "steps": [validation_result, payment_result, confirmation_result]
}
```

3. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Understanding your durable function code

Before you move to the next step, let's look at the function code and understand key durable function concepts.

- The `@durable_execution` decorator:

Your handler function is decorated with `@durable_execution`. This decorator enables durable execution by providing the `DurableContext` object and managing checkpoint operations.

- The `@durable_step` decorator:

Each step function is decorated with `@durable_step`. This decorator marks the function as a durable step that creates checkpoints.

- The `DurableContext` object:

Instead of the standard Lambda context, your function receives a `DurableContext`. This object provides methods for durable operations like `step()` and `wait()` that create checkpoints.

- Steps and checkpoints:

Each `context.step()` call creates a checkpoint before and after execution. If your function is interrupted, it resumes from the last completed checkpoint. The function doesn't re-execute completed steps. It uses their stored results instead.

- Wait operations:

The `context.wait()` call pauses execution without consuming compute resources. When the wait completes, Lambda invokes your function again and replays the checkpoint log, substituting stored values for completed steps.

- Python SDK is synchronous:

Note that the Python SDK doesn't use `await`. All durable operations are synchronous method calls.

Invoke the durable function using the console code editor

When no explicit version is specified (or published), the console invokes the durable function using the `$LATEST` version qualifier. However, for deterministic execution of your code, you must always use a qualified ARN pointing to a stable version.

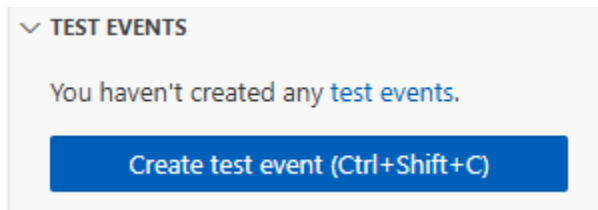

To publish a version of your function

1. Choose the **Versions** tab.
2. Choose **Publish new version**.
3. For **Version description**, enter **Initial version** (optional).
4. Choose **Publish**.
5. Lambda creates version 1 of your function. Note that the function ARN now includes `:1` at the end, indicating this is version 1.

Now create a test event to send to your function. The event is a JSON formatted document containing an order ID.

To create the test event

1. In the **TEST EVENTS** section of the console code editor, choose **Create test event**.

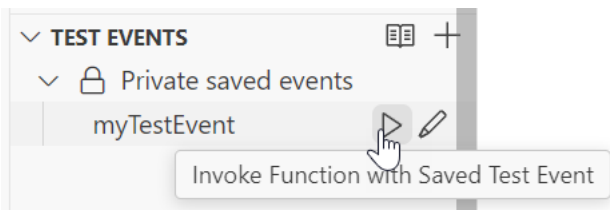

2. For **Event Name**, enter **myTestEvent**.
3. In the **Event JSON** section, replace the default JSON with the following:

```
{  
  "orderId": "order-12345"  
}
```

4. Choose **Save**.

To test your durable function and view execution

In the **TEST EVENTS** section of the console code editor, choose the run icon next to your test event:

Your durable function starts executing. Because it includes a 10-second wait, the initial invocation completes quickly, and the function resumes after the wait period. You can view the execution progress in the **Durable executions** tab.

To view your durable function execution

1. Choose the **Durable executions** tab.
2. Find your execution in the list. The execution shows the current status (Running, Succeeded, or Failed).
3. Choose the execution ID to view details, including:
 - Execution timeline showing when each step completed
 - Checkpoint history

- Wait periods
- Step results

You can also view your function's logs in CloudWatch Logs to see the console output from each step.

To view your function's invocation records in CloudWatch Logs

1. Open the [Log groups](#) page of the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/myDurableFunction`).
3. Scroll down and choose the **Log stream** for the function invocations you want to look at.

Log streams (14)			Delete	Create log stream	Search all log streams
<input type="text" value="Filter log streams or try prefix search"/>		<input type="checkbox"/> Exact match	<input type="checkbox"/> Show expired	Info	< 1 >
<input type="checkbox"/>	Log stream	Last event time			
<input type="checkbox"/>	2024/04/30/[\$LATEST]e0fa	2024-04-30 17:24:16 (UTC)			
<input type="checkbox"/>	2024/04/19/[\$LATEST]e9a	2024-04-19 20:59:06 (UTC)			
<input type="checkbox"/>	2024/02/22/[\$LATEST]cf0	2024-02-22 18:38:41 (UTC)			
<input type="checkbox"/>	2024/02/21/[1]d132c4d	2024-02-21 21:37:01 (UTC)			
<input type="checkbox"/>	2024/02/21/[1]5ad	2024-02-21 21:37:01 (UTC)			

You should see log entries for each invocation of your function, including the initial execution and the replay after the wait.

Note

When you use the logger from the `DurableContext` (such as `context.logger` or `stepContext.logger`), logs also appear in the durable execution and step views in the Lambda console. These logs may take a moment to load.

Clean up

When you're finished working with the example durable function, delete it. You can also delete the log group that stores the function's logs, and the [execution role](#) that the console created.

To delete the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Select the function that you created.
3. Choose **Actions, Delete**.
4. Type **confirm** in the text input field and choose **Delete**.

To delete the log group

1. Open the [Log groups](#) page of the CloudWatch console.
2. Select the function's log group (/aws/lambda/myDurableFunction).
3. Choose **Actions, Delete log group(s)**.
4. In the **Delete log group(s)** dialog box, choose **Delete**.

To delete the execution role

1. Open the [Roles page](#) of the AWS Identity and Access Management (IAM) console.
2. Select the function's execution role (for example, myDurableFunction-role-*31exxmpl*).
3. Choose **Delete**.
4. In the **Delete role** dialog box, enter the role name, and then choose **Delete**.

Additional resources and next steps

Now that you've created and tested a simple durable function using the console, take these next steps:

- Learn about common use cases for durable functions, including distributed transactions, order processing, and human review workflows. See [Examples](#).
- Understand how to monitor durable function executions with CloudWatch metrics and execution history. See [Monitoring and debugging](#).

- Learn about invoking durable functions synchronously and asynchronously, and managing long-running executions. See [Invoking durable functions](#).
- Follow best practices for writing deterministic code, managing checkpoint sizes, and optimizing costs. See [Best practices](#).
- Learn how to test durable functions locally and in the cloud. See [Testing durable functions](#).
- Compare durable functions with Step Functions to understand when each approach is most effective. See [Durable functions or Step Functions](#).

Deploy and invoke Lambda durable functions with the AWS CLI

Use the AWS CLI to create and deploy Lambda durable functions with imperative commands. This approach gives you direct control over each step of the deployment process.

Prerequisites

- Install and configure the AWS CLI. For instructions, see [Installing the AWS CLI](#).
- Create a deployment package with your function code and the durable execution SDK.
- Create an IAM execution role with checkpoint permissions.

Create the execution role

Create an IAM role with permissions for basic Lambda execution and checkpoint operations.

To create the execution role

1. Create a trust policy document that allows Lambda to assume the role. Save this as `trust-policy.json`:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
```

```
]
}
```

2. Create the role:

```
aws iam create-role \
  --role-name durable-function-role \
  --assume-role-policy-document file://trust-policy.json
```

3. Attach the durable execution policy for checkpoint operations and basic execution:

```
aws iam attach-role-policy \
  --role-name durable-function-role \
  --policy-arn arn:aws:iam::aws:policy/service-role/
AWSLambdaBasicDurableExecutionRolePolicy
```

The `AWSLambdaBasicDurableExecutionRolePolicy` managed policy includes the required permissions for checkpoint operations (`lambda:CheckpointDurableExecutions` and `lambda:GetDurableExecutionState`) and basic Lambda execution.

Create the durable function

Create your durable function with the `--durable-config` parameter.

To create a durable function

1. Package your function code with dependencies into a .zip file:

```
zip -r function.zip index.mjs node_modules/
```

2. Create the function with durable execution enabled:

```
aws lambda create-function \
  --function-name myDurableFunction \
  --runtime nodejs22.x \
  --role arn:aws:iam::123456789012:role/durable-function-role \
  --handler index.handler \
  --zip-file fileb://function.zip \
  --durable-config '{"ExecutionTimeout": 3600, "RetentionPeriodInDays": 7}'
```

Note

You can only enable durable execution when creating the function. You cannot enable it on existing functions.

Publish a version

While durable functions can be invoked using the `$LATEST` version qualifier, you must always use a qualified ARN pointing to a stable version to ensure deterministic execution of your code.

```
aws lambda publish-version \  
  --function-name myDurableFunction \  
  --description "Initial version"
```

The command returns the version ARN. Note the version number (for example, `:1`) at the end of the ARN.

Optionally, create an alias that points to the version:

```
aws lambda create-alias \  
  --function-name myDurableFunction \  
  --name prod \  
  --function-version 1
```

Invoke the durable function

Invoke your durable function using the qualified ARN (version or alias).

Note

Idempotent invocations: To prevent duplicate executions when retrying failed invocations, you can provide an execution name that ensures at-most-once execution semantics. See [Idempotency](#) for details.

Synchronous invocation

For executions that complete within 15 minutes, use synchronous invocation:

```
aws lambda invoke \  
  --function-name myDurableFunction:1 \  
  --payload '{"orderId": "order-12345"}' \  
  --cli-binary-format raw-in-base64-out \  
  response.json
```

Or using an alias:

```
aws lambda invoke \  
  --function-name myDurableFunction:prod \  
  --payload '{"orderId": "order-12345"}' \  
  --cli-binary-format raw-in-base64-out \  
  response.json
```

Asynchronous invocation

For long-running executions, use asynchronous invocation:

```
aws lambda invoke \  
  --function-name myDurableFunction:prod \  
  --invocation-type Event \  
  --payload '{"orderId": "order-12345"}' \  
  --cli-binary-format raw-in-base64-out \  
  response.json
```

With asynchronous invocation, Lambda returns immediately. The function continues executing in the background.

Note

You can use \$LATEST for prototyping and testing in the console. For production workloads, use a published version or alias.

Manage durable executions

Use the following commands to manage and monitor durable function executions.

List executions

List all executions for a durable function:

```
aws lambda list-durable-executions-by-function \  
  --function-name myDurableFunction
```

Get execution details

Get details about a specific execution:

```
aws lambda get-durable-execution \  
  --durable-execution-arn arn:aws:lambda:us-east-1:123456789012:function:myDurableFunction:my-function-version/durable-execution/my-execution-name/my-execution-id
```

Get execution history

View the checkpoint history for an execution:

```
aws lambda get-durable-execution-history \  
  --durable-execution-arn arn:aws:lambda:us-east-1:123456789012:function:myDurableFunction:my-function-version/durable-execution/my-execution-name/my-execution-id
```

Stop an execution

Stop a running durable execution:

```
aws lambda stop-durable-execution \  
  --durable-execution-arn arn:aws:lambda:us-east-1:123456789012:function:myDurableFunction:my-function-version/durable-execution/my-execution-name/my-execution-id
```

Update function code

Update your durable function code and publish a new version:

To update and publish a new version

1. Update the function code:

```
aws lambda update-function-code \  
  --function-name myDurableFunction \  
  --zip-file fileb://function.zip
```

2. Wait for the update to complete:

```
aws lambda wait function-updated \  
  --function-name myDurableFunction
```

3. Publish a new version:

```
aws lambda publish-version \  
  --function-name myDurableFunction \  
  --description "Updated order processing logic"
```

4. Update the alias to point to the new version:

```
aws lambda update-alias \  
  --function-name myDurableFunction \  
  --name prod \  
  --function-version 2
```

Important

Running executions continue using the version they started with. New invocations use the updated alias version.

View function logs

View your durable function's logs in CloudWatch Logs:

```
aws logs tail /aws/lambda/myDurableFunction --follow
```

Filter logs for a specific execution:

```
aws logs filter-log-events \  
  --log-group-name /aws/lambda/myDurableFunction \  
  --filter-pattern "exec-abc123"
```

Clean up resources

Delete your durable function and associated resources:

```
# Delete the function
aws lambda delete-function --function-name myDurableFunction

# Delete the IAM role policies
aws iam detach-role-policy \
  --role-name durable-function-role \
  --policy-arn arn:aws:iam::aws:policy/service-role/AWSLambdaBasicExecutionRole

aws iam detach-role-policy \
  --role-name durable-function-role \
  --policy-arn arn:aws:iam::aws:policy/service-role/
AWSLambdaBasicDurableExecutionRolePolicy

# Delete the role
aws iam delete-role --role-name durable-function-role
```

Next steps

After deploying your durable function with the AWS CLI:

- Monitor executions using the `list-durable-executions` and `get-durable-execution` commands
- View checkpoint operations in AWS CloudTrail data events
- Set up CloudWatch alarms for execution failures or long-running executions
- Automate deployments using shell scripts or CI/CD pipelines

For more information about AWS CLI commands for Lambda, see the [AWS CLI Command Reference](#).

Deploy Lambda durable functions with Infrastructure as Code

You can deploy Lambda durable functions using Infrastructure as Code (IaC) tools like AWS CloudFormation, AWS CDK, AWS Serverless Application Model, or Terraform. These tools let you define your function, execution role, and permissions in code, making deployments repeatable and version-controlled.

All three tools require you to:

- Enable durable execution on the function

- Grant checkpoint permissions to the execution role
- Publish a version or create an alias (durable functions require qualified ARNs)

AWS CloudFormation

Use CloudFormation to define your durable function in a template. The following example creates a durable function with the required permissions.

```
AWSTemplateFormatVersion: '2010-09-09'
Description: Lambda durable function example

Resources:
  DurableFunctionRole:
    Type: AWS::IAM::Role
    Properties:
      AssumeRolePolicyDocument:
        Version: '2012-10-17'
        Statement:
          - Effect: Allow
            Principal:
              Service: lambda.amazonaws.com
            Action: sts:AssumeRole
      ManagedPolicyArns:
        - arn:aws:iam::aws:policy/service-role/AWSLambdaBasicDurableExecutionRolePolicy

  DurableFunction:
    Type: AWS::Lambda::Function
    Properties:
      FunctionName: myDurableFunction
      Runtime: nodejs22.x
      Handler: index.handler
      Role: !GetAtt DurableFunctionRole.Arn
      Code:
        ZipFile: |
          // Your durable function code here
          export const handler = async (event, context) => {
            return { statusCode: 200 };
          };
      DurableConfig:
        ExecutionTimeout: 3600
        RetentionPeriodInDays: 7
```

```

DurableFunctionVersion:
  Type: AWS::Lambda::Version
  Properties:
    FunctionName: !Ref DurableFunction
    Description: Initial version

DurableFunctionAlias:
  Type: AWS::Lambda::Alias
  Properties:
    FunctionName: !Ref DurableFunction
    FunctionVersion: !GetAtt DurableFunctionVersion.Version
    Name: prod

Outputs:
  FunctionArn:
    Description: Durable function ARN
    Value: !GetAtt DurableFunction.Arn
  AliasArn:
    Description: Function alias ARN (use this for invocations)
    Value: !Ref DurableFunctionAlias

```

To deploy the template

```

aws cloudformation deploy \
  --template-file template.yaml \
  --stack-name my-durable-function-stack \
  --capabilities CAPABILITY_IAM

```

AWS CDK

AWS CDK lets you define infrastructure using programming languages. The following examples show how to create a durable function using TypeScript and Python.

TypeScript

```

import * as cdk from 'aws-cdk-lib';
import * as lambda from 'aws-cdk-lib/aws-lambda';
import * as iam from 'aws-cdk-lib/aws-iam';
import { Construct } from 'constructs';

export class DurableFunctionStack extends cdk.Stack {
  constructor(scope: Construct, id: string, props?: cdk.StackProps) {

```

```

    super(scope, id, props);

    // Create the durable function
    const durableFunction = new lambda.Function(this, 'DurableFunction', {
        runtime: lambda.Runtime.NODEJS_22_X,
        handler: 'index.handler',
        code: lambda.Code.fromAsset('lambda'),
        functionName: 'myDurableFunction',
        durableConfig: { executionTimeout: Duration.hours(1), retentionPeriod:
Duration.days(30) },
    });

    // Create version and alias
    const version = durableFunction.currentVersion;
    const alias = new lambda.Alias(this, 'ProdAlias', {
        aliasName: 'prod',
        version: version,
    });

    // Output the alias ARN
    new cdk.CfnOutput(this, 'FunctionAliasArn', {
        value: alias.functionArn,
        description: 'Use this ARN to invoke the durable function',
    });
}
}

```

Python

```

from aws_cdk import (
    Stack,
    aws_lambda as lambda_,
    aws_iam as iam,
    CfnOutput,
)
from constructs import Construct

class DurableFunctionStack(Stack):
    def __init__(self, scope: Construct, id: str, **kwargs):
        super().__init__(scope, id, **kwargs)

        # Create the durable function
        durable_function = lambda_.Function(

```

```

        self, 'DurableFunction',
        runtime=lambda_.Runtime.NODEJS_22_X,
        handler='index.handler',
        code=lambda_.Code.from_asset('lambda'),
        function_name='myDurableFunction',
        durable_execution={execution_timeout: Duration.hours(1),
retention_period: Duration.days(30)}
    )

    # Add durable execution managed policy for checkpoint permissions
    durable_function.role.add_managed_policy(
        iam.ManagedPolicy.from_aws_managed_policy_name('service-role/
AWSLambdaBasicDurableExecutionRolePolicy')
    )

    # Create version and alias
    version = durable_function.current_version
    alias = lambda_.Alias(
        self, 'ProdAlias',
        alias_name='prod',
        version=version
    )

    # Output the alias ARN
    CfnOutput(
        self, 'FunctionAliasArn',
        value=alias.function_arn,
        description='Use this ARN to invoke the durable function'
    )

```

To deploy the CDK stack

```
cdk deploy
```

AWS Serverless Application Model

AWS SAM simplifies CloudFormation templates for serverless applications. The following template creates a durable function with AWS SAM.

```

AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: Lambda durable function with SAM

```

Resources:**DurableFunction:**

Type: AWS::Serverless::Function

Properties:

FunctionName: myDurableFunction

Runtime: nodejs22.x

Handler: index.handler

CodeUri: ./src

DurableConfig:

ExecutionTimeout: 3600

RetentionPeriodInDays: 7

Policies:

- arn:aws:iam::aws:policy/service-role/AWSLambdaBasicDurableExecutionRolePolicy

AutoPublishAlias: prod

Outputs:**FunctionArn:**

Description: Durable function ARN

Value: !GetAtt DurableFunction.Arn

AliasArn:

Description: Function alias ARN (use this for invocations)

Value: !Ref DurableFunction.Alias

To deploy the SAM template

```
sam build
sam deploy --guided
```

Terraform

Terraform is a popular open-source IaC tool that supports AWS resources. The following example creates a durable function with Terraform using the AWS provider version 6.25.0 or later.

```
terraform {
  required_version = ">= 1.0"
  required_providers {
    aws = {
      source  = "hashicorp/aws"
      version = ">= 6.25.0"
    }
  }
}
```

```
provider "aws" {
  region = "us-east-2"
}

# IAM Role for Lambda Function
resource "aws_iam_role" "lambda_role" {
  name = "durable-function-role"

  assume_role_policy = jsonencode({
    Version = "2012-10-17"
    Statement = [{
      Action = "sts:AssumeRole"
      Effect = "Allow"
      Principal = {
        Service = "lambda.amazonaws.com"
      }
    }]
  })
}

# Attach durable execution policy for checkpoint operations
resource "aws_iam_role_policy_attachment" "lambda_durable" {
  policy_arn = "arn:aws:iam::aws:policy/service-role/
AWSLambdaBasicDurableExecutionRolePolicy"
  role       = aws_iam_role.lambda_role.name
}

# Lambda Function with Durable Execution enabled
resource "aws_lambda_function" "durable_function" {
  filename      = "function.zip"
  function_name = "myDurableFunction"
  role          = aws_iam_role.lambda_role.arn
  handler       = "index.handler"
  runtime       = "nodejs22.x"
  timeout       = 30
  memory_size   = 512

  durable_config {
    execution_timeout = 900
    retention_period  = 7
  }
}
```

```
# Publish a version
resource "aws_lambda_alias" "prod" {
  name           = "prod"
  function_name  = aws_lambda_function.durable_function.function_name
  function_version = aws_lambda_function.durable_function.version
}

output "function_arn" {
  description = "ARN of the Lambda function"
  value       = aws_lambda_function.durable_function.arn
}

output "alias_arn" {
  description = "ARN of the function alias (use this for invocations)"
  value       = aws_lambda_alias.prod.arn
}
```

To deploy with Terraform

```
terraform init
terraform plan
terraform apply
```

Note

Terraform support for Lambda durable functions requires AWS provider version 6.25.0 or later. Update your provider version if you're using an older version.

Common configuration patterns

Regardless of which IaC tool you use, follow these patterns for durable functions:

Enable durable execution

Set the `DurableConfig` property on your function to enable durable execution. This property is only available when creating the function. You cannot enable durable execution on existing functions.

Grant checkpoint permissions

Attach the `AWSLambdaBasicDurableExecutionRolePolicy` managed policy to the execution role. This policy includes the required `lambda:CheckpointDurableExecutions` and `lambda:GetDurableExecutionState` permissions.

Use qualified ARNs

Create a version or alias for your function. Durable functions require qualified ARNs (with version or alias) for invocation. Use `AutoPublishAlias` in AWS SAM or create explicit versions in CloudFormation, AWS CDK, and Terraform.

Package dependencies

Include the durable execution SDK in your deployment package. For Node.js, install `@aws/durable-execution-sdk-js`. For Python, install `aws-durable-execution-sdk-python`.

Next steps

After deploying your durable function:

- Test your function using the qualified ARN (version or alias)
- Monitor execution progress in the Lambda console under the Durable executions tab
- View checkpoint operations in AWS CloudTrail data events
- Review CloudWatch Logs for function output and replay behavior

For more information about deploying Lambda functions with IaC tools, see:

- [CloudFormation AWS::Lambda::Function reference](#)
- [AWS CDK Lambda module documentation](#)
- [AWS SAM Developer Guide](#)

Durable functions or Step Functions

Both Lambda durable functions and AWS Step Functions enable reliable workflow orchestration with automatic state management and failure recovery. They serve different developer preferences and architectural patterns. Durable functions are optimized for application development within Lambda, while Step Functions is built for workflow orchestration across AWS services.

When to use durable functions

Use durable functions when:

- Your team prefers standard programming languages and familiar development tools
- Your application logic is primarily within Lambda functions
- You want fine-grained control over execution state in code
- You're building Lambda-centric applications with tight coupling between workflow and business logic
- You want to iterate quickly without switching between code and visual/JSON designers

When to use Step Functions

Use Step Functions when:

- You need visual workflow representation for cross-team visibility
- You're orchestrating multiple AWS services and want native integrations without custom SDK code
- You require zero-maintenance infrastructure (no patching, runtime updates)
- Non-technical stakeholders need to understand and validate workflow logic

Decision framework

Use the following questions to determine which service fits your use case:

- **What's your primary focus?** Application development in Lambda → durable functions. Workflow orchestration across AWS → Step Functions.
- **What's your preferred programming model?** Standard programming languages → durable functions. Graph-based DSL or visual designer → Step Functions.
- **How many AWS services are involved?** Primarily Lambda → durable functions. Multiple AWS services → Step Functions.
- **What development tools do you use?** Lambda developer experience, IDE with LLM agent, programming language-specific unit test frameworks, AWS SAM, AWS CDK, AWS Toolkit → durable functions. Visual workflow builder, AWS CDK to model workflows → Step Functions.

- **Who manages the infrastructure?** Want flexibility within Lambda → durable functions. Want fully managed, zero-maintenance → Step Functions.

Feature comparison

The following table compares key features between Step Functions and Lambda durable functions:

Feature	AWS Step Functions	Lambda durable functions
Primary focus	Workflow orchestration across AWS	Application development in Lambda
Service type	Standalone, dedicated workflow service	Runs within Lambda
Programming model	Graph-based, Amazon States Language DSL or AWS CDK	Standard programming languages (JavaScript/TypeScript, Python)
Development tools	Visual builder in Console / AWS Toolkit IDE extension, AWS CDK	Lambda DX within IDE and LLM agents, unit test frameworks, AWS SAM, AWS Toolkit IDE extension
Integrations	220+ AWS services, 16k APIs	Lambda event-driven programming model extension (event sources)
Management	Fully managed, runtime agnostic, zero maintenance (no patching, runtime updates)	Managed within Lambda environment
Best for	Business process and IT automation, data processing, AI workflows	Distributed transactions, stateful application logic, function orchestration, data processing, AI workflows

Hybrid architectures

Many applications benefit from using both services. A common pattern is using durable functions for application-level logic within Lambda, while Step Functions coordinates high-level workflows across multiple AWS services beyond Lambda functions.

Migration considerations

Starting simple, evolving complex: Begin with durable functions for Lambda-centric workflows. Add Step Functions when you need multi-service orchestration or visual workflow design.

Existing Step Functions users: Keep Step Functions for established cross-service workflows. Consider durable functions for new Lambda application logic that needs reliability.

- [Getting started with durable functions](#)

Examples and use cases

Lambda durable functions enable you to build fault-tolerant, multi-step applications using durable operations like steps and waits. With automatic checkpointing and a checkpoint-replay model, where execution restarts from the beginning after failure but skips completed checkpoints, your functions can recover from failures and resume execution without losing progress.

Short-lived fault-tolerant processes

Use durable functions to build reliable operations that typically complete within minutes. While these processes are shorter than long-running workflows, they still benefit from automatic checkpointing and fault tolerance across distributed systems. Durable functions ensure your multi-step processes complete successfully even when individual service calls fail, without requiring complex error handling or state management code.

Common scenarios include hotel booking systems, restaurant reservation platforms, ride-sharing trip requests, event ticket purchases, and SaaS subscription upgrades. These scenarios share common characteristics: multiple service calls that must complete together, the need for automatic

retry on transient failures, and the requirement to maintain consistent state across distributed systems.

Distributed transactions across microservices

Coordinate payments, inventory, and shipping across multiple services with automatic rollback on failures. Each service operation is wrapped in a step, ensuring the transaction can recover from any point if a service fails.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { orderId, amount, items } = event;

    // Reserve inventory across multiple warehouses
    const inventory = await context.step("reserve-inventory", async () => {
      return await inventoryService.reserve(items);
    });

    // Process payment
    const payment = await context.step("process-payment", async () => {
      return await paymentService.charge(amount);
    });

    // Create shipment
    const shipment = await context.step("create-shipment", async () => {
      return await shippingService.createShipment(orderId, inventory);
    });

    return { orderId, status: 'completed', shipment };
  }
);
```

Python

```
from aws_durable_execution_sdk_python import DurableContext, durable_execution
```

```
@durable_execution
def lambda_handler(event, context: DurableContext):
    order_id = event['orderId']
    amount = event['amount']
    items = event['items']

    # Reserve inventory across multiple warehouses
    inventory = context.step(
        lambda _: inventory_service.reserve(items),
        name='reserve-inventory'
    )

    # Process payment
    payment = context.step(
        lambda _: payment_service.charge(amount),
        name='process-payment'
    )

    # Create shipment
    shipment = context.step(
        lambda _: shipping_service.create_shipment(order_id, inventory),
        name='create-shipment'
    )

    return {'orderId': order_id, 'status': 'completed', 'shipment': shipment}
```

If any step fails, the function automatically retries from the last successful checkpoint. The inventory reservation persists even if payment processing fails temporarily. When the function retries, it skips the completed inventory step and proceeds directly to payment processing. This eliminates duplicate reservations and ensures consistent state across your distributed system.

Order processing with multiple steps

Process orders through validation, payment authorization, inventory allocation, and fulfillment with automatic retry and recovery. Each step is checkpointed, ensuring the order progresses even if individual steps fail and retry.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-
js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { orderId, customerId, items } = event;

    // Validate order details
    const validation = await context.step("validate-order", async () => {
      const customer = await customerService.validate(customerId);
      const itemsValid = await inventoryService.validateItems(items);
      return { customer, itemsValid };
    });

    if (!validation.itemsValid) {
      return { orderId, status: 'rejected', reason: 'invalid_items' };
    }

    // Authorize payment
    const authorization = await context.step("authorize-payment", async () => {
      return await paymentService.authorize(
        validation.customer.paymentMethod,
        calculateTotal(items)
      );
    });

    // Allocate inventory
    const allocation = await context.step("allocate-inventory", async () => {
      return await inventoryService.allocate(items);
    });

    // Fulfill order
    const fulfillment = await context.step("fulfill-order", async () => {
      return await fulfillmentService.createShipment({
        orderId,
        items: allocation.allocatedItems,
        address: validation.customer.shippingAddress
      });
    });

    return {
      orderId,
      status: 'completed',
      trackingNumber: fulfillment.trackingNumber
    }
  }
);
```

```
};
}
);
```

Python

```
from aws_durable_execution_sdk_python import DurableContext, durable_execution

@durable_execution
def lambda_handler(event, context: DurableContext):
    order_id = event['orderId']
    customer_id = event['customerId']
    items = event['items']

    # Validate order details
    def validate_order(_):
        customer = customer_service.validate(customer_id)
        items_valid = inventory_service.validate_items(items)
        return {'customer': customer, 'itemsValid': items_valid}

    validation = context.step(validate_order, name='validate-order')

    if not validation['itemsValid']:
        return {'orderId': order_id, 'status': 'rejected', 'reason':
'invalid_items'}

    # Authorize payment
    authorization = context.step(
        lambda _: payment_service.authorize(
            validation['customer']['paymentMethod'],
            calculate_total(items)
        ),
        name='authorize-payment'
    )

    # Allocate inventory
    allocation = context.step(
        lambda _: inventory_service.allocate(items),
        name='allocate-inventory'
    )
```

```
# Fulfill order
fulfillment = context.step(
    lambda _: fulfillment_service.create_shipment({
        'orderId': order_id,
        'items': allocation['allocatedItems'],
        'address': validation['customer']['shippingAddress']
    }),
    name='fulfill-order'
)

return {
    'orderId': order_id,
    'status': 'completed',
    'trackingNumber': fulfillment['trackingNumber']
}
```

This pattern ensures orders never get stuck in intermediate states. If validation fails, the order is rejected before payment authorization. If payment authorization fails, inventory isn't allocated. Each step builds on the previous one with automatic retry and recovery.

Note

The conditional check `if (!validation.itemsValid)` is outside a step and will re-execute during replay. This is safe because it's deterministic—it always produces the same result given the same validation object.

Long-running processes

Use durable functions for processes that span hours, days, or weeks. Wait operations suspend execution without incurring compute charges, making long-running processes cost-effective. During wait periods, your function stops running and Lambda recycles the execution environment. When it's time to resume, Lambda invokes your function again and replays from the last checkpoint.

This execution model makes durable functions ideal for processes that need to pause for extended periods, whether waiting for human decisions, external system responses, scheduled processing windows, or time-based delays. You pay only for active compute time, not for waiting.

Common scenarios include document approval processes, scheduled batch processing, multi-day onboarding processes, subscription trial processes, and delayed notification systems. These

scenarios share common characteristics: extended wait periods measured in hours or days, the need to maintain execution state across those waits, and cost-sensitive requirements where paying for idle compute time is prohibitive.

Human-in-the-loop approvals

Pause execution for document reviews, approvals, or decisions while maintaining execution state. The function waits for external callbacks without consuming resources, resuming automatically when approval is received.

This pattern is essential for processes that require human judgment or external validation. The function suspends at the callback point, incurring no compute charges while waiting. When someone submits their decision via API, Lambda invokes your function again and replays from the checkpoint, continuing with the approval result.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { documentId, reviewers } = event;

    // Step 1: Prepare document for review
    const prepared = await context.step("prepare-document", async () => {
      return await documentService.prepare(documentId);
    });

    // Step 2: Request approval with callback
    const approval = await context.waitForCallback(
      "approval-callback",
      async (callbackId) => {
        await notificationService.sendApprovalRequest({
          documentId,
          reviewers,
          callbackId,
          expiresIn: 86400
        });
      },
      {

```

```

        timeout: { seconds: 86400 }
    }
);

// Function resumes here when approval is received
if (approval?.approved) {
    const finalized = await context.step("finalize-document", async () => {
        return await documentService.finalize(documentId, approval.comments);
    });

    return {
        status: 'approved',
        documentId,
        finalizedAt: finalized.timestamp
    };
}

// Handle rejection
await context.step("archive-rejected", async () => {
    await documentService.archive(documentId, approval?.reason);
});

return {
    status: 'rejected',
    documentId,
    reason: approval?.reason
};
}
);

```

Python

```

from aws_durable_execution_sdk_python import DurableContext, durable_execution,
WaitConfig

@durable_execution
def lambda_handler(event, context: DurableContext):
    document_id = event['documentId']
    reviewers = event['reviewers']

    # Step 1: Prepare document for review

```

```
prepared = context.step(
    lambda _: document_service.prepare(document_id),
    name='prepare-document'
)

# Step 2: Request approval with callback
def send_approval_request(callback_id):
    notification_service.send_approval_request({
        'documentId': document_id,
        'reviewers': reviewers,
        'callbackId': callback_id,
        'expiresIn': 86400
    })

approval = context.wait_for_callback(
    send_approval_request,
    name='approval-callback',
    config=WaitConfig(timeout=86400)
)

# Function resumes here when approval is received
if approval and approval.get('approved'):
    finalized = context.step(
        lambda _: document_service.finalize(document_id,
approval.get('comments')),
        name='finalize-document'
    )

    return {
        'status': 'approved',
        'documentId': document_id,
        'finalizedAt': finalized['timestamp']
    }

# Handle rejection
context.step(
    lambda _: document_service.archive(document_id, approval.get('reason') if
approval else None),
    name='archive-rejected'
)

return {
    'status': 'rejected',
    'documentId': document_id,
```

```
    'reason': approval.get('reason') if approval else None
  }
```

When the callback is received and your function resumes, it replays from the beginning. The prepare-document step returns its checkpointed result instantly. The waitForCallback operation also returns instantly with the stored approval result instead of waiting again. Execution then continues to the finalization or archival steps.

Multi-stage data pipelines

Process large datasets through extraction, transformation, and loading phases with checkpoints between stages. Each stage can take hours to complete, and checkpoints ensure the pipeline can resume from any stage if interrupted.

This pattern is ideal for ETL workflows, data migrations, or batch processing jobs where you need to process data in stages with recovery points between them. If a stage fails, the pipeline resumes from the last completed stage rather than restarting from the beginning. You can also use wait operations to pause between stages; respecting rate limits, waiting for downstream systems to be ready, or scheduling processing during off-peak hours.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { datasetId, batchSize } = event;

    // Stage 1: Extract data from source
    const extracted = await context.step("extract-data", async () => {
      const records = await sourceDatabase.extractRecords(datasetId);
      return { recordCount: records.length, records };
    });

    // Wait 5 minutes to respect source system rate limits
    await context.wait({ seconds: 300 });

    // Stage 2: Transform data in batches
```

```
const transformed = await context.step("transform-data", async () => {
    const batches = chunkArray(extracted.records, batchSize);
    const results = [];

    for (const batch of batches) {
        const transformed = await transformService.processBatch(batch);
        results.push(transformed);
    }

    return { batchCount: batches.length, results };
});

// Wait until off-peak hours (e.g., 2 AM)
const now = new Date();
const targetHour = 2;
const msUntilTarget = calculateMsUntilHour(now, targetHour);
await context.wait({ seconds: Math.floor(msUntilTarget / 1000) });

// Stage 3: Load data to destination
const loaded = await context.step("load-data", async () => {
    let loadedCount = 0;

    for (const result of transformed.results) {
        await destinationDatabase.loadBatch(result);
        loadedCount += result.length;
    }

    return { loadedCount };
});

// Stage 4: Verify and finalize
const verified = await context.step("verify-pipeline", async () => {
    const verification = await destinationDatabase.verifyRecords(datasetId);
    await pipelineService.markComplete(datasetId, verification);
    return verification;
});

return {
    datasetId,
    recordsProcessed: extracted.recordCount,
    batchesProcessed: transformed.batchCount,
    recordsLoaded: loaded.loadedCount,
    verified: verified.success
};
```

```
}
);
```

Python

```
from aws_durable_execution_sdk_python import DurableContext, durable_execution
from datetime import datetime

@durable_execution
def lambda_handler(event, context: DurableContext):
    dataset_id = event['datasetId']
    batch_size = event['batchSize']

    # Stage 1: Extract data from source
    def extract_data(_):
        records = source_database.extract_records(dataset_id)
        return {'recordCount': len(records), 'records': records}

    extracted = context.step(extract_data, name='extract-data')

    # Wait 5 minutes to respect source system rate limits
    context.wait(300)

    # Stage 2: Transform data in batches
    def transform_data(_):
        batches = chunk_array(extracted['records'], batch_size)
        results = []

        for batch in batches:
            transformed = transform_service.process_batch(batch)
            results.append(transformed)

        return {'batchCount': len(batches), 'results': results}

    transformed = context.step(transform_data, name='transform-data')

    # Wait until off-peak hours (e.g., 2 AM)
    now = datetime.now()
    target_hour = 2
    ms_until_target = calculate_ms_until_hour(now, target_hour)
    context.wait(ms_until_target // 1000)
```

```
# Stage 3: Load data to destination
def load_data(_):
    loaded_count = 0

    for result in transformed['results']:
        destination_database.load_batch(result)
        loaded_count += len(result)

    return {'loadedCount': loaded_count}

loaded = context.step(load_data, name='load-data')

# Stage 4: Verify and finalize
def verify_pipeline(_):
    verification = destination_database.verify_records(dataset_id)
    pipeline_service.mark_complete(dataset_id, verification)
    return verification

verified = context.step(verify_pipeline, name='verify-pipeline')

return {
    'datasetId': dataset_id,
    'recordsProcessed': extracted['recordCount'],
    'batchesProcessed': transformed['batchCount'],
    'recordsLoaded': loaded['loadedCount'],
    'verified': verified['success']
}
```

Each stage is wrapped in a step, creating a checkpoint that allows the pipeline to resume from any stage if interrupted. The 5-minute wait between extract and transform respects source system rate limits without consuming compute resources, while the wait until 2 AM schedules the expensive load operation during off-peak hours.

Note

The new `Date()` call and `calculateMsUntilHour()` function are outside steps and will re-execute during replay. For time-based operations that must be consistent across replays, calculate the timestamp inside a step or use it only for wait durations (which are checkpointed).

Advanced patterns

Use durable functions to build complex multi-step applications that combine multiple durable operations, parallel execution, array processing, conditional logic, and polling. These patterns let you build sophisticated applications that coordinate many tasks while maintaining fault tolerance and automatic recovery.

Advanced patterns go beyond simple sequential steps. You can run operations concurrently with `parallel()`, process arrays with `map()`, wait for external conditions with `waitForCondition()`, and combine these primitives to build reliable applications. Each durable operation creates its own checkpoints, so your application can recover from any point if interrupted.

User onboarding processes

Guide users through registration, email verification, profile setup, and initial configuration with retry handling. This example combines sequential steps, callbacks, and conditional logic to create a complete onboarding process.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { userId, email } = event;

    // Step 1: Create user account
    const user = await context.step("create-account", async () => {
      return await userService.createAccount(userId, email);
    });

    // Step 2: Send verification email
    await context.step("send-verification", async () => {
      return await emailService.sendVerification(email);
    });

    // Step 3: Wait for email verification (up to 48 hours)
    const verified = await context.waitForCallback(
      "email-verification",
      async (callbackId) => {
```

```
        await notificationService.sendVerificationLink({
            email,
            callbackId,
            expiresIn: 172800
        });
    },
    {
        timeout: { seconds: 172800 }
    }
);

if (!verified) {
    await context.step("send-reminder", async () => {
        await emailService.sendReminder(email);
    });

    return {
        status: "verification_timeout",
        userId,
        message: "Email verification not completed within 48 hours"
    };
}

// Step 4: Initialize user profile in parallel
const setupResults = await context.parallel("profile-setup", [
    async (ctx: DurableContext) => {
        return await ctx.step("create-preferences", async () => {
            return await preferencesService.createDefaults(userId);
        });
    },

    async (ctx: DurableContext) => {
        return await ctx.step("setup-notifications", async () => {
            return await notificationService.setupDefaults(userId);
        });
    },

    async (ctx: DurableContext) => {
        return await ctx.step("create-welcome-content", async () => {
            return await contentService.createWelcome(userId);
        });
    }
]);
```

```
// Step 5: Send welcome email
await context.step("send-welcome", async () => {
    const [preferences, notifications, content] = setupResults.getResults();
    return await emailService.sendWelcome({
        email,
        preferences,
        notifications,
        content
    });
});

return {
    status: "onboarding_complete",
    userId,
    completedAt: new Date().toISOString()
};
}
);
```

Python

```
from aws_durable_execution_sdk_python import DurableContext, durable_execution,
    WaitConfig
from datetime import datetime

@durable_execution
def lambda_handler(event, context: DurableContext):
    user_id = event['userId']
    email = event['email']

    # Step 1: Create user account
    user = context.step(
        lambda _: user_service.create_account(user_id, email),
        name='create-account'
    )

    # Step 2: Send verification email
    context.step(
        lambda _: email_service.send_verification(email),
        name='send-verification'
    )
```

```
# Step 3: Wait for email verification (up to 48 hours)
def send_verification_link(callback_id):
    notification_service.send_verification_link({
        'email': email,
        'callbackId': callback_id,
        'expiresIn': 172800
    })

verified = context.wait_for_callback(
    send_verification_link,
    name='email-verification',
    config=WaitConfig(timeout=172800)
)

if not verified:
    context.step(
        lambda _: email_service.send_reminder(email),
        name='send-reminder'
    )

    return {
        'status': 'verification_timeout',
        'userId': user_id,
        'message': 'Email verification not completed within 48 hours'
    }

# Step 4: Initialize user profile in parallel
def create_preferences(ctx: DurableContext):
    return ctx.step(
        lambda _: preferences_service.create_defaults(user_id),
        name='create-preferences'
    )

def setup_notifications(ctx: DurableContext):
    return ctx.step(
        lambda _: notification_service.setup_defaults(user_id),
        name='setup-notifications'
    )

def create_welcome_content(ctx: DurableContext):
    return ctx.step(
        lambda _: content_service.create_welcome(user_id),
        name='create-welcome-content'
```

```

    )

    setup_results = context.parallel(
        [create_preferences, setup_notifications, create_welcome_content],
        name='profile-setup'
    )

    # Step 5: Send welcome email
    def send_welcome(_):
        results = setup_results.get_results()
        preferences, notifications, content = results[0], results[1], results[2]
        return email_service.send_welcome({
            'email': email,
            'preferences': preferences,
            'notifications': notifications,
            'content': content
        })

    context.step(send_welcome, name='send-welcome')

    return {
        'status': 'onboarding_complete',
        'userId': user_id,
        'completedAt': datetime.now().isoformat()
    }

```

The process combines sequential steps with checkpoints for account creation and email sending, then pauses for up to 48 hours waiting for email verification without consuming resources. Conditional logic handles different paths based on whether verification completes or times out. Profile setup tasks run concurrently using parallel operations to reduce total execution time, and each step retries automatically on transient failures to ensure the onboarding completes reliably.

Chained invocations across functions

Invoke other Lambda functions from within a durable function using `context.invoke()`. The calling function suspends while waiting for the invoked function to complete, creating a checkpoint that preserves the result. If the calling function is interrupted after the invoked function completes, it resumes with the stored result without re-invoking the function.

Use this pattern when you have specialized functions that handle specific domains (customer validation, payment processing, inventory management) and need to coordinate them in a workflow. Each function maintains its own logic and can be invoked by multiple orchestrator functions, avoiding code duplication.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

// Main orchestrator function
export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { orderId, customerId } = event;

    // Step 1: Validate customer by invoking customer service function
    const customer = await context.invoke(
      "validate-customer",
      "arn:aws:lambda:us-east-1:123456789012:function:customer-service:1",
      { customerId }
    );

    if (!customer.isValid) {
      return { orderId, status: "rejected", reason: "invalid_customer" };
    }

    // Step 2: Check inventory by invoking inventory service function
    const inventory = await context.invoke(
      "check-inventory",
      "arn:aws:lambda:us-east-1:123456789012:function:inventory-service:1",
      { orderId, items: event.items }
    );

    if (!inventory.available) {
      return { orderId, status: "rejected", reason: "insufficient_inventory" };
    }

    // Step 3: Process payment by invoking payment service function
    const payment = await context.invoke(
      "process-payment",
      "arn:aws:lambda:us-east-1:123456789012:function:payment-service:1",
      {
```

```

        customerId,
        amount: inventory.totalAmount,
        paymentMethod: customer.paymentMethod
    }
};

// Step 4: Create shipment by invoking fulfillment service function
const shipment = await context.invoke(
    "create-shipment",
    "arn:aws:lambda:us-east-1:123456789012:function:fulfillment-service:1",
    {
        orderId,
        items: inventory.allocatedItems,
        address: customer.shippingAddress
    }
);

return {
    orderId,
    status: "completed",
    trackingNumber: shipment.trackingNumber,
    estimatedDelivery: shipment.estimatedDelivery
};
}
);

```

Python

```

from aws_durable_execution_sdk_python import DurableContext, durable_execution

# Main orchestrator function
@durable_execution
def lambda_handler(event, context: DurableContext):
    order_id = event['orderId']
    customer_id = event['customerId']

    # Step 1: Validate customer by invoking customer service function
    customer = context.invoke(
        'arn:aws:lambda:us-east-1:123456789012:function:customer-service:1',
        {'customerId': customer_id},
        name='validate-customer'
    )

```

```
)

if not customer['isValid']:
    return {'orderId': order_id, 'status': 'rejected', 'reason':
'invalid_customer'}

# Step 2: Check inventory by invoking inventory service function
inventory = context.invoke(
    'arn:aws:lambda:us-east-1:123456789012:function:inventory-service:1',
    {'orderId': order_id, 'items': event['items']},
    name='check-inventory'
)

if not inventory['available']:
    return {'orderId': order_id, 'status': 'rejected', 'reason':
'insufficient_inventory'}

# Step 3: Process payment by invoking payment service function
payment = context.invoke(
    'arn:aws:lambda:us-east-1:123456789012:function:payment-service:1',
    {
        'customerId': customer_id,
        'amount': inventory['totalAmount'],
        'paymentMethod': customer['paymentMethod']
    },
    name='process-payment'
)

# Step 4: Create shipment by invoking fulfillment service function
shipment = context.invoke(
    'arn:aws:lambda:us-east-1:123456789012:function:fulfillment-service:1',
    {
        'orderId': order_id,
        'items': inventory['allocatedItems'],
        'address': customer['shippingAddress']
    },
    name='create-shipment'
)

return {
    'orderId': order_id,
    'status': 'completed',
    'trackingNumber': shipment['trackingNumber'],
    'estimatedDelivery': shipment['estimatedDelivery']
}
```

```
}
```

Each invocation creates a checkpoint in the orchestrator function. If the orchestrator is interrupted after the customer validation completes, it resumes from that checkpoint with the stored customer data, skipping the validation invocation. This prevents duplicate calls to downstream services and ensures consistent execution across interruptions.

The invoked functions can be either durable or standard Lambda functions. If you invoke a durable function, it can have its own multi-step workflow with waits and checkpoints. The orchestrator simply waits for the complete durable execution to finish, receiving the final result.

Note

Cross-account invocations are not supported. All invoked functions must be in the same AWS account as the calling function.

Batch processing with checkpoints

Process millions of records with automatic recovery from the last successful checkpoint after failures. This example demonstrates how durable functions combine `map()` operations with chunking and rate limiting to handle large-scale data processing.

TypeScript

```
import { DurableContext, withDurableExecution } from "@aws/durable-execution-sdk-js";

interface Batch {
  batchIndex: number;
  recordIds: string[];
}

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    const { datasetId, batchSize = 1000 } = event;

    // Step 1: Get all record IDs to process
```

```

const recordIds = await context.step("fetch-record-ids", async () => {
    return await dataService.getRecordIds(datasetId);
});

// Step 2: Split into batches
const batches: Batch[] = [];
for (let i = 0; i < recordIds.length; i += batchSize) {
    batches.push({
        batchIndex: Math.floor(i / batchSize),
        recordIds: recordIds.slice(i, i + batchSize)
    });
}

// Step 3: Process batches with controlled concurrency
const batchResults = await context.map(
    "process-batches",
    batches,
    async (ctx: DurableContext, batch: Batch, index: number) => {
        const processed = await ctx.step(`batch-${batch.batchIndex}`, async () => {
            const results = [];
            for (const recordId of batch.recordIds) {
                const result = await recordService.process(recordId);
                results.push(result);
            }
            return results;
        });

        const validated = await ctx.step(`validate-${batch.batchIndex}`, async () =>
    {
        return await validationService.validateBatch(processed);
    });

        return {
            batchIndex: batch.batchIndex,
            recordCount: batch.recordIds.length,
            successCount: validated.successCount,
            failureCount: validated.failureCount
        };
    },
    {
        maxConcurrency: 5
    }
);

```

```
// Step 4: Aggregate results
const summary = await context.step("aggregate-results", async () => {
  const results = batchResults.getResults();
  const totalSuccess = results.reduce((sum, r) => sum + r.successCount, 0);
  const totalFailure = results.reduce((sum, r) => sum + r.failureCount, 0);

  return {
    datasetId,
    totalRecords: recordIds.length,
    batchesProcessed: batches.length,
    successCount: totalSuccess,
    failureCount: totalFailure,
    completedAt: new Date().toISOString()
  };
});

return summary;
}
);
```

Python

```
from aws_durable_execution_sdk_python import DurableContext, durable_execution,
    MapConfig
from datetime import datetime
from typing import List, Dict

@durable_execution
def lambda_handler(event, context: DurableContext):
    dataset_id = event['datasetId']
    batch_size = event.get('batchSize', 1000)

    # Step 1: Get all record IDs to process
    record_ids = context.step(
        lambda _: data_service.get_record_ids(dataset_id),
        name='fetch-record-ids'
    )

    # Step 2: Split into batches
    batches = []
    for i in range(0, len(record_ids), batch_size):
```

```

    batches.append({
        'batchIndex': i // batch_size,
        'recordIds': record_ids[i:i + batch_size]
    })

# Step 3: Process batches with controlled concurrency
def process_batch(ctx: DurableContext, batch: Dict, index: int):
    batch_index = batch['batchIndex']

    def process_records(_):
        results = []
        for record_id in batch['recordIds']:
            result = record_service.process(record_id)
            results.append(result)
        return results

    processed = ctx.step(process_records, name=f'batch-{batch_index}')

    validated = ctx.step(
        lambda _: validation_service.validate_batch(processed),
        name=f'validate-{batch_index}'
    )

    return {
        'batchIndex': batch_index,
        'recordCount': len(batch['recordIds']),
        'successCount': validated['successCount'],
        'failureCount': validated['failureCount']
    }

batch_results = context.map(
    process_batch,
    batches,
    name='process-batches',
    config=MapConfig(max_concurrency=5)
)

# Step 4: Aggregate results
def aggregate_results(_):
    results = batch_results.get_results()
    total_success = sum(r['successCount'] for r in results)
    total_failure = sum(r['failureCount'] for r in results)

    return {

```

```
        'datasetId': dataset_id,  
        'totalRecords': len(record_ids),  
        'batchesProcessed': len(batches),  
        'successCount': total_success,  
        'failureCount': total_failure,  
        'completedAt': datetime.now().isoformat()  
    }  
  
    summary = context.step(aggregate_results, name='aggregate-results')  
  
    return summary
```

Records are split into manageable batches to avoid overwhelming memory or downstream services, then multiple batches process concurrently with `maxConcurrency` controlling the parallelism. Each batch has its own checkpoint, so failures only retry the failed batch rather than reprocessing all records. This pattern is ideal for ETL jobs, data migrations, or bulk operations where processing can take hours.

Security and permissions for Lambda durable functions

Lambda durable functions require specific IAM permissions to manage checkpoint operations. Follow the principle of least privilege by granting only the permissions your function needs.

Execution role permissions

Your durable function's execution role needs permissions to create checkpoints and retrieve execution state. The following policy shows the minimum required permissions:

```
{
```

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "lambda:CheckpointDurableExecution",
        "lambda:GetDurableExecutionState"
      ],
      "Resource": "arn:aws:lambda:region:account-id:function:function-name:*"
    }
  ]
}
```

When you create a durable function using the console, Lambda automatically adds these permissions to the execution role. If you create the function using the AWS CLI or AWS CloudFormation, add these permissions to your execution role.

Least privilege principle

Scope the Resource element to specific function ARNs instead of using wildcards. This limits the execution role to checkpoint operations for only the functions that need them.

Example: Scoped permissions for multiple functions

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "lambda:CheckpointDurableExecution",
        "lambda:GetDurableExecutionState"
      ],
      "Resource": [
        "arn:aws:lambda:us-east-1:123456789012:function:orderProcessor:*",
        "arn:aws:lambda:us-east-1:123456789012:function:paymentHandler:*"
      ]
    }
  ]
}
```

Alternatively, you can use the AWS managed policy `AWSLambdaBasicDurableExecutionRolePolicy` which includes the required durable

execution permissions along with basic Lambda execution permissions for Amazon CloudWatch Logs.

State encryption

Lambda durable functions automatically enable encryption at rest using AWS owned keys at no charge. Each function execution maintains isolated state that other executions cannot access. Customer managed keys (CMK) are not supported.

Checkpoint data includes:

- Step results and return values
- Execution progress and timeline
- Wait state information

All data is encrypted in transit using TLS when Lambda reads or writes checkpoint data.

Custom encryption with custom serializers and deserializers

For critical security requirements, you can implement your own encryption and decryption mechanism using custom serializers and deserializers (SerDer) using durable SDK. This approach gives you full control over the encryption keys and algorithms used to protect checkpoint data.

Important

When you use custom encryption, you lose visibility of operation results in the Lambda console and API responses. Checkpoint data appears encrypted in execution history and cannot be inspected without decryption.

Your function's execution role needs `kms:Encrypt` and `kms:Decrypt` permissions for the AWS KMS key used in the custom SerDer implementation.

CloudTrail logging

Lambda logs checkpoint operations as data events in AWS CloudTrail. You can use CloudTrail to audit when checkpoints are created, track execution state changes, and monitor access to durable execution data.

Checkpoint operations appear in CloudTrail logs with the following event names:

- `CheckpointDurableExecution` - Logged when a step completes and creates a checkpoint
- `GetDurableExecutionState` - Logged when Lambda retrieves execution state during replay

To enable data event logging for durable functions, configure a CloudTrail trail to log Lambda data events. For more information, see [Logging data events](#) in the CloudTrail User Guide.

Example: CloudTrail log entry for checkpoint operation

```
{
  "eventVersion": "1.08",
  "eventTime": "2024-11-16T10:30:45Z",
  "eventName": "CheckpointDurableExecution",
  "eventSource": "lambda.amazonaws.com",
  "requestParameters": {
    "functionName": "myDurableFunction",
    "executionId": "exec-abc123",
    "stepId": "step-1"
  },
  "responseElements": null,
  "eventType": "AwsApiCall"
}
```

Cross-account considerations

If you invoke durable functions across AWS accounts, the calling account needs `lambda:InvokeFunction` permission, but checkpoint operations always use the execution role in the function's account. The calling account cannot access checkpoint data or execution state directly.

This isolation ensures that checkpoint data remains secure within the function's account, even when invoked from external accounts.

Inherited Lambda security features

Durable functions inherit all security, governance, and compliance features from Lambda, including VPC connectivity, environment variable encryption, dead letter queues, reserved concurrency, function URLs, code signing, and compliance certifications (SOC, PCI DSS, HIPAA, etc.).

For detailed information about Lambda security features, see [Security in AWS Lambda](#) in the Lambda Developer Guide. The only additional security considerations for durable functions are the checkpoint permissions documented in this guide.

Durable execution SDK

The durable execution SDK is the foundation for building durable functions. It provides the primitives you need to checkpoint progress, handle retries, and manage execution flow. The SDK abstracts the complexity of checkpoint management and replay, letting you write sequential code that automatically becomes fault-tolerant.

The SDK is available for JavaScript, TypeScript, and Python. For complete API documentation and examples, see the [JavaScript/TypeScript SDK](#) and [Python SDK](#) on GitHub.

DurableContext

The SDK provides your function with a `DurableContext` object that exposes all durable operations. This context replaces the standard Lambda context and provides methods for creating checkpoints, managing execution flow, and coordinating with external systems.

To use the SDK, wrap your Lambda handler with the durable execution wrapper:

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-js';

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    // Your function receives DurableContext instead of Lambda context
    // Use context.step(), context.wait(), etc.
    return result;
  }
);
```

Python

```
from aws_durable_execution_sdk_python import durable_execution, DurableContext

@durable_execution
def handler(event: dict, context: DurableContext):
    # Your function receives DurableContext
    # Use context.step(), context.wait(), etc.
    return result
```

The wrapper intercepts your function invocation, loads any existing checkpoint log, and provides the `DurableContext` that manages replay and checkpointing.

What the SDK does

The SDK handles three critical responsibilities that enable durable execution:

Checkpoint management: The SDK automatically creates checkpoints as your function executes durable operations. Each checkpoint records the operation type, inputs, and results. When your function completes a step, the SDK persists the checkpoint before continuing. This ensures your function can resume from any completed operation if interrupted.

Replay coordination: When your function resumes after a pause or interruption, the SDK performs replay. It runs your code from the beginning but skips completed operations, using stored checkpoint results instead of re-executing them. The SDK ensures replay is deterministic—given the same inputs and checkpoint log, your function produces the same results.

State isolation: The SDK maintains execution state separately from your business logic. Each durable execution has its own checkpoint log that other executions cannot access. The SDK encrypts checkpoint data at rest and ensures state remains consistent across replays.

How checkpointing works

When you call a durable operation, the SDK follows this sequence:

1. **Check for existing checkpoint:** The SDK checks if this operation already completed in a previous invocation. If a checkpoint exists, the SDK returns the stored result without re-executing the operation.
2. **Execute the operation:** If no checkpoint exists, the SDK executes your operation code. For steps, this means calling your function. For waits, this means scheduling resumption.

3. **Create checkpoint:** After the operation completes, the SDK serializes the result and creates a checkpoint. The checkpoint includes the operation type, name, inputs, result, and timestamp.
4. **Persist checkpoint:** The SDK calls the Lambda checkpoint API to persist the checkpoint. This ensures the checkpoint is durable before continuing execution.
5. **Return result:** The SDK returns the operation result to your code, which continues to the next operation.

This sequence ensures that once an operation completes, its result is safely stored. If your function is interrupted at any point, the SDK can replay up to the last completed checkpoint.

Replay behavior

When your function resumes after a pause or interruption, the SDK performs replay:

1. **Load checkpoint log:** The SDK retrieves the checkpoint log for this execution from Lambda.
2. **Run from beginning:** The SDK invokes your handler function from the start, not from where it paused.
3. **Skip completed durable operations:** As your code calls durable operations, the SDK checks each against the checkpoint log. For completed durable operations, the SDK returns the stored result without executing the operation code.

Note

If a child context's result was larger than the maximum checkpoint size (256 KB), the context's code is executed again during replay. This allows you to construct large results from the durable operations that ran inside the context, which will be looked up from the checkpoint log. Therefore it is imperative to only run deterministic code in the context itself. When using child contexts with large results, it is a best practice to perform long-running or non-deterministic work inside of steps and only perform short-running tasks which combine the results in the context itself.

4. **Resume at interruption point:** When the SDK reaches an operation without a checkpoint, it executes normally and creates new checkpoints as durable operations complete.

This replay mechanism requires your code to be deterministic. Given the same inputs and checkpoint log, your function must make the same sequence of durable operation calls. The SDK enforces this by validating that operation names and types match the checkpoint log during replay.

Available durable operations

The `DurableContext` provides operations for different coordination patterns. Each durable operation creates checkpoints automatically, ensuring your function can resume from any point.

Steps

Executes business logic with automatic checkpointing and retry. Use steps for operations that call external services, perform calculations, or execute any logic that should be checkpointed. The SDK creates a checkpoint before and after the step, storing the result for replay.

TypeScript

```
const result = await context.step('process-payment', async () => {
  return await paymentService.charge(amount);
});
```

Python

```
result = context.step(
    lambda _: payment_service.charge(amount),
    name='process-payment'
)
```

Steps support configurable retry strategies, execution semantics (at-most-once or at-least-once), and custom serialization.

Waits

Pauses execution for a specified duration without consuming compute resources. The SDK creates a checkpoint, terminates the function invocation, and schedules resumption. When the wait

completes, Lambda invokes your function again and the SDK replays to the wait point before continuing.

TypeScript

```
// Wait 1 hour without charges
await context.wait({ seconds: 3600 });
```

Python

```
# Wait 1 hour without charges
context.wait(3600)
```

Callbacks

Callbacks enable your function to pause and wait for external systems to provide input. When you create a callback, the SDK generates a unique callback ID and creates a checkpoint. Your function then suspends (terminates the invocation) without incurring compute charges. External systems submit callback results using the `SendDurableExecutionCallbackSuccess` or `SendDurableExecutionCallbackFailure` Lambda APIs. When a callback is submitted, Lambda invokes your function again, the SDK replays to the callback point, and your function continues with the callback result.

The SDK provides two methods for working with callbacks:

createCallback: Creates a callback and returns both a promise and a callback ID. You send the callback ID to an external system, which submits the result using the Lambda API.

TypeScript

```
const [promise, callbackId] = await context.createCallback('approval', {
  timeout: { hours: 24 }
});
```

```
await sendApprovalRequest(callbackId, requestData);
const approval = await promise;
```

Python

```
callback = context.create_callback(
    name='approval',
    config=CallbackConfig(timeout_seconds=86400)
)

context.step(
    lambda _: send_approval_request(callback.callback_id),
    name='send_request'
)

approval = callback.result()
```

waitForCallback: Simplifies callback handling by combining callback creation and submission in one operation. The SDK creates the callback, executes your submitter function with the callback ID, and waits for the result.

TypeScript

```
const result = await context.waitForCallback(
    'external-api',
    async (callbackId, ctx) => {
        await submitToExternalAPI(callbackId, requestData);
    },
    { timeout: { minutes: 30 } }
);
```

Python

```
result = context.wait_for_callback(
    lambda callback_id: submit_to_external_api(callback_id, request_data),
```

```
    name='external-api',  
    config=WaitForCallbackConfig(timeout_seconds=1800)  
)
```

Configure timeouts to prevent functions from waiting indefinitely. If a callback times out, the SDK throws a `CallbackError` and your function can handle the timeout case. Use heartbeat timeouts for long-running callbacks to detect when external systems stop responding.

Use callbacks for human-in-the-loop workflows, external system integration, webhook responses, or any scenario where execution must pause for external input.

Parallel execution

Executes multiple operations concurrently with optional concurrency control. The SDK manages parallel execution, creates checkpoints for each operation, and handles failures according to your completion policy.

TypeScript

```
const results = await context.parallel([  
  async (ctx) => ctx.step('task1', async () => processTask1()),  
  async (ctx) => ctx.step('task2', async () => processTask2()),  
  async (ctx) => ctx.step('task3', async () => processTask3())  
]);
```

Python

```
results = context.parallel(  
    lambda ctx: ctx.step(lambda _: process_task1(), name='task1'),  
    lambda ctx: ctx.step(lambda _: process_task2(), name='task2'),  
    lambda ctx: ctx.step(lambda _: process_task3(), name='task3')  
)
```

Use `parallel` to execute independent operations concurrently.

Map

Concurrently execute an operation on each item in an array with optional concurrency control. The SDK manages concurrent execution, creates checkpoints for each operation, and handles failures according to your completion policy.

TypeScript

```
const results = await context.map(itemArray, async (ctx, item, index) =>
  ctx.step('task', async () => processItem(item, index))
);
```

Python

```
results = context.map(
    item_array,
    lambda ctx, item, index: ctx.step(
        lambda _: process_item(item, index),
        name='task'
    )
)
```

Use map to process arrays with concurrency control.

Child contexts

Creates an isolated execution context for grouping operations. Child contexts have their own checkpoint log and can contain multiple steps, waits, and other operations. The SDK treats the entire child context as a single unit for retry and recovery.

Use child contexts to organize complex workflows, implement sub-workflows, or isolate operations that should retry together.

TypeScript

```
const result = await context.runInChildContext(
```

```
'batch-processing',
async (childCtx) => {
  return await processBatch(childCtx, items);
}
);
```

Python

```
result = context.run_in_child_context(
    lambda child_ctx: process_batch(child_ctx, items),
    name='batch-processing'
)
```

The replay mechanism demands that durable operations happen in a deterministic order. Using multiple child contexts you can have multiple streams of work execute concurrently, and the determinism applies separately within each context. This allows you to build high-performance functions which efficiently utilize multiple CPU cores.

For example, imagine we start two child contexts, A and B. On the initial invocation, the steps within the contexts were run in this order, with the 'A' steps running concurrently with the 'B' steps: A1, B1, B2, A2, A3. Upon replay, the timing is much faster as results are retrieved from checkpoint log, and the steps happen to be encountered in a different order: B1, A1, A2, B2, A3. Because the 'A' steps were encountered in the correct order (A1, A2, A3) and the 'B' steps were encountered in the correct order (B1, B2), the need for determinism was satisfied correctly.

Conditional waits

Polls for a condition with automatic checkpointing between attempts. The SDK executes your check function, creates a checkpoint with the result, waits according to your strategy, and repeats until the condition is met.

TypeScript

```
const result = await context.waitForCondition(
  async (state, ctx) => {
    const status = await checkJobStatus(state.jobId);
```

```

    return { ...state, status };
  },
  {
    initialState: { jobId: 'job-123', status: 'pending' },
    waitStrategy: (state) =>
      state.status === 'completed'
        ? { shouldContinue: false }
        : { shouldContinue: true, delay: { seconds: 30 } }
  }
);

```

Python

```

result = context.wait_for_condition(
    lambda state, ctx: check_job_status(state['jobId']),
    config=WaitForConditionConfig(
        initial_state={'jobId': 'job-123', 'status': 'pending'},
        wait_strategy=lambda state, attempt:
            {'should_continue': False} if state['status'] == 'completed'
            else {'should_continue': True, 'delay': 30}
    )
)

```

Use `waitForCondition` for polling external systems, waiting for resources to be ready, or implementing retry with backoff.

Function invocation

Invokes another Lambda function and waits for its result. The SDK creates a checkpoint, invokes the target function, and resumes your function when the invocation completes. This enables function composition and workflow decomposition.

TypeScript

```

const result = await context.invoke(
    'invoke-processor',
    'arn:aws:lambda:us-east-1:123456789012:function:processor:1',

```

```
{ data: inputData }  
);
```

Python

```
result = context.invoke(  
    'arn:aws:lambda:us-east-1:123456789012:function:processor:1',  
    {'data': input_data},  
    name='invoke-processor'  
)
```

How durable operations are metered

Each durable operation you call through `DurableContext` creates checkpoints to track execution progress and store state data. These operations incur charges based on their usage, and the checkpoints may contain data that contributes to your data write and retention costs. Stored data includes invocation event data, payloads returned from steps, and data passed when completing callbacks. Understanding how durable operations are metered helps you estimate execution costs and optimize your workflows. For details on pricing, see the [Lambda pricing page](#).

Payload size refers to the size of the serialized data that a durable operation persists. The data is measured in bytes and the size can vary depending on the serializer used by the operation. The payload of an operation could be the result itself for successful completions, or the serialized error object if the operation failed.

Basic operations

Basic operations are the fundamental building blocks for durable functions:

Operation	Checkpoint timing	Number of operations	Data persisted
Execution	Started	1	Input payload size

Operation	Checkpoint timing	Number of operations	Data persisted
Execution	Completed (Succeeded/Failed/Stopped)	0	Output payload size
Step	Retry/Succeeded/Failed	1 + N retries	Returned payload size from each attempt
Wait	Started	1	N/A
WaitForCondition	Each poll attempt	1 + N polls	Returned payload size from each poll attempt
Invocation-level Retry	Started	1	Payload for error object

Callback operations

Callback operations enable your function to pause and wait for external systems to provide input. These operations create checkpoints when the callback is created and when it's completed:

Operation	Checkpoint timing	Number of operations	Data persisted
CreateCallback	Started	1	N/A
Callback completion via API call	Completed	0	Callback payload
WaitForCallback	Started	3 + N retries (context +	Payloads returned by submitter step attempts, plus two copies of the callback payload

Operation	Checkpoint timing	Number of operations	Data persisted
		callback + step)	

Compound operations

Compound operations combine multiple durable operations to handle complex coordination patterns like parallel execution, array processing, and nested contexts:

Operation	Checkpoint timing	Number of operations	Data persisted
Parallel	Started	1 + N branches (1 parent context + N child contexts)	Up to two copies of the returned payload size from each branch, plus the statuses of each branch
Map	Started	1 + N branches (1 parent context + N child contexts)	Up to two copies of the returned payload size from each iteration, plus the statuses of each iteration
Promise helpers	Completed	1	Returned payload size from the promise
RunInChildContext	Succeeded/Failed	1	Returned payload size from the child context

For contexts, such as from `runInChildContext` or used internally by compound operations, results smaller than 256 KB are checkpointed directly. Larger results aren't stored—instead, they're reconstructed during replay by re-processing the context's operations.

Supported runtimes for durable functions

Durable functions are available for Node.js and Python runtimes. You can create durable functions using managed runtimes in the Lambda console or deploy them using container images for additional runtime version flexibility.

Lambda managed runtimes

The following managed runtimes support durable functions when you create functions in the Lambda console or using the AWS CLI with the `--durable-config '{"ExecutionTimeout": 3600, "RetentionPeriodInDays": 7}'` parameter. For complete information about Lambda runtimes, see [Lambda runtimes](#).

Language	Runtime
Node.js	nodejs22.x
Node.js	nodejs24.x
Python	python3.13
Python	python3.14

Note

Lambda runtimes include the durable execution SDK for testing and development. However, we recommend including the SDK in your deployment package for production. This ensures version consistency and avoids potential runtime updates that might affect your function behavior.

Node.js

Install the SDK in your Node.js project:

```
npm install @aws/durable-execution-sdk-js
```

The SDK supports JavaScript and TypeScript. For TypeScript projects, the SDK includes type definitions.

Python

Install the SDK in your Python project:

```
pip install aws-durable-execution-sdk-python
```

The Python SDK uses synchronous methods and doesn't require `async/await`.

Container images

You can use durable functions with container images to support additional runtime versions or custom runtime configurations. Container images let you use runtime versions not available as managed runtimes or customize your runtime environment.

To create a durable function using a container image:

1. Create a Dockerfile based on an Lambda base image
2. Install the durable execution SDK in your container
3. Build and push the container image to Amazon Elastic Container Registry
4. Create the Lambda function from the container image with durable execution enabled

Python container example

Create a Dockerfile for Python 3.11:

```
FROM public.ecr.aws/lambda/python:3.11

# Copy requirements file
```

```
COPY requirements.txt ${LAMBDA_TASK_ROOT}/

# Install dependencies including durable SDK
RUN pip install -r requirements.txt

# Copy function code
COPY lambda_function.py ${LAMBDA_TASK_ROOT}/

# Set the handler
CMD [ "lambda_function.handler" ]
```

Create a `requirements.txt` file:

```
aws-durable-execution-sdk-python
```

Build and push the image:

```
# Build the image
docker build -t my-durable-function .

# Tag for ECR
docker tag my-durable-function:latest 123456789012.dkr.ecr.us-east-1.amazonaws.com/my-durable-function:latest

# Push to ECR
docker push 123456789012.dkr.ecr.us-east-1.amazonaws.com/my-durable-function:latest
```

Create the function with durable execution enabled:

```
aws lambda create-function \
  --function-name myDurableFunction \
  --package-type Image \
  --code ImageUri=123456789012.dkr.ecr.us-east-1.amazonaws.com/my-durable-function:latest \
  --role arn:aws:iam::123456789012:role/lambda-execution-role \
  --durable-config '{"ExecutionTimeout": 3600, "RetentionPeriodInDays": 7}'
```

For more information about using container images with Lambda, see [Creating Lambda container images](#) in the Lambda Developer Guide.

Runtime considerations

SDK version management: Include the durable execution SDK in your deployment package or container image. This ensures your function uses a specific SDK version and isn't affected by runtime updates. Pin SDK versions in your `package.json` or `requirements.txt` to control when you upgrade.

Runtime updates: AWS updates managed runtimes to include security patches and bug fixes. These updates may include new SDK versions. To avoid unexpected behavior, include the SDK in your deployment package and test thoroughly before deploying to production.

Container image size: Container images have a maximum uncompressed size of 10 GB. The durable execution SDK adds minimal size to your image. Optimize your container by using multi-stage builds and removing unnecessary dependencies.

Cold start performance: Container images may have longer cold start times than managed runtimes. The durable execution SDK has minimal impact on cold start performance. Use provisioned concurrency if cold start latency is critical for your application.

Invoking durable Lambda functions

Durable Lambda functions support the same invocation methods as standard Lambda functions. You can invoke durable functions synchronously, asynchronously, or through event source mappings. The invocation process is identical to standard functions, but durable functions provide additional capabilities for long-running executions and automatic state management.

Invocation methods

Synchronous invocation: Invoke a durable function and wait for the response. Synchronous invocations are limited by the Lambda to 15 minutes (or less, depending on the configured function and execution timeout). Use synchronous invocation when you need immediate results or when integrating with APIs and services that expect a response. You can use wait operations for efficient computation without disrupting the caller—the invocation waits for the entire durable

execution to complete. For idempotent execution starts, use the execution name parameter as described in [Idempotency](#).

```
aws lambda invoke \  
  --function-name my-durable-function:1 \  
  --cli-binary-format raw-in-base64-out \  
  --payload '{"orderId": "12345"}' \  
  response.json
```

Asynchronous invocation: Queue an event for processing without waiting for a response. Lambda places the event in a queue and returns immediately. Asynchronous invocations support execution durations up to 1 year. Use asynchronous invocation for fire-and-forget scenarios or when processing can happen in the background. For idempotent execution starts, use the execution name parameter as described in [Idempotency](#).

```
aws lambda invoke \  
  --function-name my-durable-function:1 \  
  --invocation-type Event \  
  --cli-binary-format raw-in-base64-out \  
  --payload '{"orderId": "12345"}' \  
  response.json
```

Event source mappings: Configure Lambda to automatically invoke your durable function when records are available from stream or queue-based services like Amazon SQS, Kinesis, or DynamoDB. Event source mappings poll the event source and invoke your function with batches of records. For details about using event source mappings with durable functions, including execution duration limits, see [Event source mappings with durable functions](#).

For complete details about each invocation method, see [synchronous invocation](#) and [asynchronous invocation](#).

Note

Durable functions support dead-letter queues (DLQs) for error handling, but don't support Lambda destinations. Configure a DLQ to capture records from failed invocations.

Qualified ARNs requirement

Durable functions require qualified identifiers for invocation. You must invoke durable functions using a version number, alias, or `$LATEST`. You can use either a full qualified ARN or a function name with version/alias suffix. You cannot use an unqualified identifier (without a version or alias suffix).

Valid invocations:

```
# Using full ARN with version number
arn:aws:lambda:us-east-1:123456789012:function:my-durable-function:1

# Using full ARN with alias
arn:aws:lambda:us-east-1:123456789012:function:my-durable-function:prod

# Using full ARN with $LATEST
arn:aws:lambda:us-east-1:123456789012:function:my-durable-function:$LATEST

# Using function name with version number
my-durable-function:1

# Using function name with alias
my-durable-function:prod
```

Invalid invocations:

```
# Unqualified ARN (not allowed)
arn:aws:lambda:us-east-1:123456789012:function:my-durable-function

# Unqualified function name (not allowed)
my-durable-function
```

This requirement ensures that durable executions remain consistent throughout their lifecycle. When a durable execution starts, it's pinned to the specific function version. If your function pauses and resumes hours or days later, Lambda invokes the same version that started the execution, ensuring code consistency across the entire workflow.

Best practice

Use numbered versions or aliases for production durable functions rather than `$LATEST`. Numbered versions are immutable and ensure deterministic replay. Optionally, aliases provide a stable reference that you can update to point to new versions without changing invocation code. When you update an alias, new executions use the new version, while in-progress executions continue with their original version. You may use `$LATEST` for prototyping or to shorten deployment times during development, understanding that executions might not replay correctly (or even fail) if the underlying code changes during running executions.

Understanding execution lifecycle

When you invoke a durable function, Lambda creates a durable execution that can span multiple function invocations:

1. **Initial invocation:** Your invocation request creates a new durable execution. Lambda assigns a unique execution ID and starts processing.
2. **Execution and checkpointing:** As your function executes durable operations, the SDK creates checkpoints that track progress.
3. **Suspension (if needed):** If your function uses durable waits, such as `wait` or `waitForCallback`, or automatic step retries, Lambda suspends the execution and stops charging for compute time.
4. **Resumption:** When it's time to resume (including after retries), Lambda invokes your function again. The SDK replays the checkpoint log and continues from where execution paused.
5. **Completion:** When your function returns a final result or throws an unhandled error, the durable execution completes.

For synchronous invocations, the caller waits for the entire durable execution to complete, including any wait operations. If the execution exceeds the invocation timeout (15 minutes or less), the invocation times out. For asynchronous invocations, Lambda returns immediately and the execution continues independently. Use the durable execution APIs to track execution status and retrieve final results.

Invoking from application code

Use the AWS SDKs to invoke durable functions from your application code. The invocation process is identical to standard functions:

TypeScript

```
import { LambdaClient, InvokeCommand } from '@aws-sdk/client-lambda';

const client = new LambdaClient({});

// Synchronous invocation
const response = await client.send(new InvokeCommand({
  FunctionName: 'arn:aws:lambda:us-east-1:123456789012:function:my-durable-
function:1',
  Payload: JSON.stringify({ orderId: '12345' })
}));

const result = JSON.parse(Buffer.from(response.Payload!).toString());

// Asynchronous invocation
await client.send(new InvokeCommand({
  FunctionName: 'arn:aws:lambda:us-east-1:123456789012:function:my-durable-
function:1',
  InvocationType: 'Event',
  Payload: JSON.stringify({ orderId: '12345' })
}));
```

Python

```
import boto3
import json

client = boto3.client('lambda')

# Synchronous invocation
response = client.invoke(
    FunctionName='arn:aws:lambda:us-east-1:123456789012:function:my-durable-
function:1',
    Payload=json.dumps({'orderId': '12345'})
)

result = json.loads(response['Payload'].read())

# Asynchronous invocation
```

```
client.invoke(  
    FunctionName='arn:aws:lambda:us-east-1:123456789012:function:my-durable-  
function:1',  
    InvocationType='Event',  
    Payload=json.dumps({'orderId': '12345'})  
)
```

Chained invocations

Durable functions can invoke other durable and non-durable functions using the `invoke` operation from `DurableContext`. This creates a chained invocation where the calling function waits (suspends) for the invoked function to complete:

TypeScript

```
export const handler = withDurableExecution(  
    async (event: any, context: DurableContext) => {  
        // Invoke another durable function and wait for result  
        const result = await context.invoke(  
            'process-order',  
            'arn:aws:lambda:us-east-1:123456789012:function:order-processor:1',  
            { orderId: event.orderId }  
        );  
  
        return { statusCode: 200, body: JSON.stringify(result) };  
    }  
);
```

Python

```
@durable_execution  
def handler(event, context: DurableContext):  
    # Invoke another durable function and wait for result  
    result = context.invoke(  
        'arn:aws:lambda:us-east-1:123456789012:function:order-processor:1',  
        {'orderId': event['orderId']},  
        name='process-order'
```

```
)  
  
return {'statusCode': 200, 'body': json.dumps(result)}
```

Chained invocations create a checkpoint in the calling function. If the calling function is interrupted, it resumes from the checkpoint with the invoked function's result, without re-invoking the function.

 **Note**

Cross-account chained invocations are not supported. The invoked function must be in the same AWS account as the calling function.

Event source mappings with durable functions

Durable functions work with all Lambda event source mappings. Configure event source mappings for durable functions the same way you configure them for standard functions. Event source mappings automatically poll event sources like Amazon SQS, Kinesis, and DynamoDB Streams, and invoke your function with batches of records.

Event source mappings are useful for durable functions that process streams or queues with complex, multi-step workflows. For example, you can create a durable function that processes Amazon SQS messages with retries, external API calls, and human approvals.

How event source mappings invoke durable functions

Event source mappings invoke durable functions synchronously, waiting for the complete durable execution to finish before processing the next batch or marking records as processed. If the total durable execution time exceeds 15 minutes, the execution times out and fails. The event source mapping receives a timeout exception and handles it according to its retry configuration.

15-minute execution limit

When durable functions are invoked by event source mappings, the total durable execution duration cannot exceed 15 minutes. This limit applies to the entire durable execution from start to completion, not just individual function invocations.

This 15-minute limit is separate from the Lambda function timeout (also 15 minutes maximum). The function timeout controls how long each individual invocation can run, while the durable execution timeout controls the total elapsed time from execution start to completion.

Example scenarios:

- **Valid:** A durable function processes an Amazon SQS message with three steps, each taking 2 minutes, then waits 5 minutes before completing a final step. Total execution time: 11 minutes. This works because the total is under 15 minutes.
- **Invalid:** A durable function processes an Amazon SQS message, completes initial processing in 2 minutes, then waits 20 minutes for an external callback before completing. Total execution time: 22 minutes. This exceeds the 15-minute limit and will fail.
- **Invalid:** A durable function processes a Kinesis record with multiple wait operations totaling 30 minutes between steps. Even though each individual invocation completes quickly, the total execution time exceeds 15 minutes.

Important

Configure your durable execution timeout to 15 minutes or less when using event source mappings, otherwise creation of the event source mapping will fail. If your workflow requires longer execution times, use the intermediary function pattern described below.

Configuring event source mappings

Configure event source mappings for durable functions using the Lambda console, AWS CLI, or AWS SDKs. All standard event source mapping properties apply to durable functions:

```
aws lambda create-event-source-mapping \  
  --function-name arn:aws:lambda:us-east-1:123456789012:function:my-durable-function:1  
 \  
  --event-source-arn arn:aws:sqs:us-east-1:123456789012:my-queue \  
  --batch-size 10 \  
  --maximum-batching-window-in-seconds 5
```

Remember to use a qualified ARN (with version number or alias) when configuring event source mappings for durable functions.

Error handling with event source mappings

Event source mappings provide built-in error handling that works with durable functions:

- **Retry behavior:** If the initial invocation fails, the event source mapping retries according to its retry configuration. Configure maximum retry attempts and retry intervals based on your requirements.
- **Dead-letter queues:** Configure a dead-letter queue to capture records that fail after all retries. This prevents message loss and enables manual inspection of failed records.
- **Partial batch failures:** For Amazon SQS and Kinesis, use partial batch failure reporting to process records individually and only retry failed records.
- **Bisect on error:** For Kinesis and DynamoDB Streams, enable bisect on error to split failed batches and isolate problematic records.

Note

Durable functions support dead-letter queues (DLQs) for error handling, but don't support Lambda destinations. Configure a DLQ to capture records from failed invocations.

For complete information about event source mapping error handling, see [event source mappings](#).

Using an intermediary function for long-running workflows

If your workflow requires more than 15 minutes to complete, use an intermediary standard Lambda function between the event source mapping and your durable function. The intermediary function receives events from the event source mapping and invokes the durable function asynchronously, removing the 15-minute execution limit.

This pattern decouples the event source mapping's synchronous invocation model from the durable function's long-running execution model. The event source mapping invokes the intermediary function, which quickly returns after starting the durable execution. The durable function then runs independently for as long as needed (up to 1 year).

Architecture

The intermediary function pattern uses three components:

1. **Event source mapping:** Polls the event source (Amazon SQS, Kinesis, DynamoDB Streams) and invokes the intermediary function synchronously with batches of records.
2. **Intermediary function:** A standard Lambda function that receives events from the event source mapping, validates and transforms the data if needed, and invokes the durable function asynchronously. This function completes quickly (typically under 1 second) and returns control to the event source mapping.
3. **Durable function:** Processes the event with complex, multi-step logic that can run for extended periods. Invoked asynchronously, so it's not constrained by the 15-minute limit.

Implementation

The intermediary function receives the entire event from the event source mapping and invokes the durable function asynchronously. Use the execution name parameter to ensure idempotent execution starts, preventing duplicate processing if the event source mapping retries:

TypeScript

```
import { LambdaClient, InvokeCommand } from '@aws-sdk/client-lambda';
import { SQSEvent } from 'aws-lambda';
import { createHash } from 'crypto';

const lambda = new LambdaClient({});

export const handler = async (event: SQSEvent) => {
  // Invoke durable function asynchronously with execution name
  await lambda.send(new InvokeCommand({
    FunctionName: 'arn:aws:lambda:us-east-1:123456789012:function:my-durable-
function:1',
    InvocationType: 'Event',
    Payload: JSON.stringify({
      executionName: event.Name,
      event: event
    })
  }));

  return { statusCode: 200 };
};
```

```
};
```

Python

```
import boto3
import json
import hashlib

lambda_client = boto3.client('lambda')

def handler(event, context):
    # Invoke durable function asynchronously with execution name
    lambda_client.invoke(
        FunctionName='arn:aws:lambda:us-east-1:123456789012:function:my-durable-
function:1',
        InvocationType='Event',
        Payload=json.dumps({
            'executionName': execution_name,
            'event': event["name"]
        })
    )

    return {'statusCode': 200}
```

For idempotency in the intermediary function itself, use [Powertools for AWS Lambda](#) to prevent duplicate invocations of the durable function if the event source mapping retries the intermediary function.

The durable function receives the payload with the execution name and processes all records with long-running logic:

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-
js';

export const handler = withDurableExecution(
    async (payload: any, context: DurableContext) => {
```

```

const sqsEvent = payload.event;

// Process each record with complex, multi-step logic
const results = await context.map(
  sqsEvent.Records,
  async (ctx, record) => {
    const validated = await ctx.step('validate', async () => {
      return validateOrder(JSON.parse(record.body));
    });

    // Wait for external approval (could take hours or days)
    const approval = await ctx.waitForCallback(
      'approval',
      async (callbackId) => {
        await requestApproval(callbackId, validated);
      },
      { timeout: { hours: 48 } }
    );

    // Complete processing
    return await ctx.step('complete', async () => {
      return completeOrder(validated, approval);
    });
  }
);

return { statusCode: 200, processed: results.getResults().length };
}
);

```

Python

```

from aws_durable_execution_sdk_python import durable_execution, DurableContext
import json

@durable_execution
def handler(payload, context: DurableContext):
    sqs_event = payload['event']

    # Process each record with complex, multi-step logic
    def process_record(ctx, record):

```

```
    validated = ctx.step(
        lambda _: validate_order(json.loads(record['body'])),
        name='validate'
    )

    # Wait for external approval (could take hours or days)
    approval = ctx.wait_for_callback(
        lambda callback_id: request_approval(callback_id, validated),
        name='approval',
        config=WaitForCallbackConfig(timeout_seconds=172800) # 48 hours
    )

    # Complete processing
    return ctx.step(
        lambda _: complete_order(validated, approval),
        name='complete'
    )

results = context.map(sqs_event['Records'], process_record)

return {'statusCode': 200, 'processed': len(results.get_results())}
```

Key considerations

This pattern removes the 15-minute execution limit by decoupling the event source mapping from the durable execution. The intermediary function returns immediately after starting the durable execution, allowing the event source mapping to continue processing. The durable function then runs independently for as long as needed.

The intermediary function succeeds when it invokes the durable function, not when the durable execution completes. If the durable execution fails later, the event source mapping won't retry because it already processed the batch successfully. Implement error handling in the durable function and configure dead-letter queues for failed executions.

Use the execution name parameter to ensure idempotent execution starts. If the event source mapping retries the intermediary function, the durable function won't start a duplicate execution because the execution name already exists.

Supported event sources

Durable functions support all Lambda event sources that use event source mappings:

- Amazon SQS queues (standard and FIFO)
- Kinesis streams
- DynamoDB Streams
- Amazon Managed Streaming for Apache Kafka (Amazon MSK)
- Self-managed Apache Kafka
- Amazon MQ (ActiveMQ and RabbitMQ)
- Amazon DocumentDB change streams

All event source types are subject to the 15-minute durable execution limit when invoking durable functions.

Retries for Lambda durable functions

Durable functions provide automatic retry capabilities that make your applications resilient to transient failures. The SDK handles retries at two levels: step retries for business logic failures and backend retries for infrastructure failures.

Step retries

When an uncaught exception occurs within a step, the SDK automatically retries the step based on the configured retry strategy. Step retries are checkpointed operations that allow the SDK to suspend execution and resume later without losing progress.

Step retry behavior

The following table describes how the SDK handles exceptions within steps:

Scenario	What happens	Metering impact
Exception in step with remaining retry attempts	The SDK creates a checkpoint for the retry and suspends the function. On the next invocation, the step retries with the configured backoff delay.	1 operation + error payload size

Scenario	What happens	Metering impact
Exception in step with no remaining retry attempts	The step fails and throws an exception. If your handler code doesn't catch this exception, the entire execution fails.	1 operation + error payload size

When a step needs to retry, the SDK checkpoints the retry state and exits the Lambda invocation if no other work is running. This allows the SDK to implement backoff delays without consuming compute resources. The function resumes automatically after the backoff period.

Configuring step retry strategies

Configure retry strategies to control how steps handle failures. You can specify maximum attempts, backoff intervals, and conditions for retrying.

Exponential backoff with max attempts:

TypeScript

```
const result = await context.step('call-api', async () => {
  const response = await fetch('https://api.example.com/data');
  if (!response.ok) throw new Error(`API error: ${response.status}`);
  return await response.json();
}, {
  retryStrategy: (error, attemptCount) => {
    if (attemptCount >= 5) {
      return { shouldRetry: false };
    }
    // Exponential backoff: 2s, 4s, 8s, 16s, 32s (capped at 300s)
    const delay = Math.min(2 * Math.pow(2, attemptCount - 1), 300);
    return { shouldRetry: true, delay: { seconds: delay } };
  }
});
```

Python

```
def retry_strategy(error, attempt_count):
    if attempt_count >= 5:
        return {'should_retry': False}
    # Exponential backoff: 2s, 4s, 8s, 16s, 32s (capped at 300s)
    delay = min(2 * (2 ** (attempt_count - 1)), 300)
    return {'should_retry': True, 'delay': delay}

result = context.step(
    lambda _: call_external_api(),
    name='call-api',
    config=StepConfig(retry_strategy=retry_strategy)
)
```

Fixed interval backoff:

TypeScript

```
const orders = await context.step('query-orders', async () => {
    return await queryDatabase(event.userId);
}, {
    retryStrategy: (error, attemptCount) => {
        if (attemptCount >= 3) {
            return { shouldRetry: false };
        }
        return { shouldRetry: true, delay: { seconds: 5 } };
    }
});
```

Python

```
def retry_strategy(error, attempt_count):
    if attempt_count >= 3:
        return {'should_retry': False}
    return {'should_retry': True, 'delay': 5}

orders = context.step(
    lambda _: query_database(event['userId']),
    name='query-orders',
```

```
    config=StepConfig(retry_strategy=retry_strategy)
)
```

Conditional retry (retry only specific errors):

TypeScript

```
const result = await context.step('call-rate-limited-api', async () => {
    const response = await fetch('https://api.example.com/data');

    if (response.status === 429) throw new Error('RATE_LIMIT');
    if (response.status === 504) throw new Error('TIMEOUT');
    if (!response.ok) throw new Error(`API_ERROR_${response.status}`);

    return await response.json();
}, {
    retryStrategy: (error, attemptCount) => {
        // Only retry rate limits and timeouts
        const isRetryable = error.message === 'RATE_LIMIT' || error.message ===
'TIMEOUT';

        if (!isRetryable || attemptCount >= 3) {
            return { shouldRetry: false };
        }

        // Exponential backoff: 1s, 2s, 4s (capped at 30s)
        const delay = Math.min(Math.pow(2, attemptCount - 1), 30);
        return { shouldRetry: true, delay: { seconds: delay } };
    }
});
```

Python

```
def retry_strategy(error, attempt_count):
    # Only retry rate limits and timeouts
    is_retryable = str(error) in ['RATE_LIMIT', 'TIMEOUT']

    if not is_retryable or attempt_count >= 3:
```

```

        return {'should_retry': False}

    # Exponential backoff: 1s, 2s, 4s (capped at 30s)
    delay = min(2 ** (attempt_count - 1), 30)
    return {'should_retry': True, 'delay': delay}

result = context.step(
    lambda _: call_rate_limited_api(),
    name='call-rate-limited-api',
    config=StepConfig(retry_strategy=retry_strategy)
)

```

Disable retries:

TypeScript

```

const isDuplicate = await context.step('check-duplicate', async () => {
    return await checkIfOrderExists(event.orderId);
}, {
    retryStrategy: () => ({ shouldRetry: false })
});

```

Python

```

is_duplicate = context.step(
    lambda _: check_if_order_exists(event['orderId']),
    name='check-duplicate',
    config=StepConfig(
        retry_strategy=lambda error, attempt: {'should_retry': False}
    )
)

```

When the retry strategy returns `shouldRetry: false`, the step fails immediately without retries. Use this for operations that should not be retried, such as idempotency checks or operations with side effects that cannot be safely repeated.

Exceptions outside steps

When an uncaught exception occurs in your handler code but outside any step, the SDK marks the execution as failed. This ensures errors in your application logic are properly captured and reported.

Scenario	What happens	Metering impact
Exception in handler code outside any step	The SDK marks the execution as FAILED and returns the error. The exception is not automatically retried.	Error payload size

To enable automatic retry for error-prone code, wrap it in a step with a retry strategy. Steps provide automatic retry with configurable backoff, while code outside steps fails immediately.

Backend retries

Backend retries occur when Lambda encounters infrastructure failures, runtime errors, or when the SDK cannot communicate with the durable execution service. Lambda automatically retries these failures to ensure your durable functions can recover from transient infrastructure issues.

Backend retry scenarios

Lambda automatically retries your function when it encounters the following scenarios:

- **Internal service errors** - When Lambda or the durable execution service returns a 5xx error, indicating a temporary service issue.
- **Throttling** - When your function is throttled due to concurrency limits or service quotas.
- **Timeouts** - When the SDK cannot reach the durable execution service within the timeout period.
- **Sandbox initialization failures** - When Lambda cannot initialize the execution environment.
- **Runtime errors** - When the Lambda runtime encounters errors outside your function code, such as out-of-memory errors or process crashes.
- **Invalid checkpoint token errors** - When the checkpoint token is no longer valid, typically due to service-side state changes.

The following table describes how the SDK handles these scenarios:

Scenario	What happens	Metering impact
Runtime error outside durable handler (OOM, timeout, crash)	Lambda automatically retries the invocation. The SDK replays from the last checkpoint, skipping completed steps.	Error payload size + 1 operation per retry
Service error (5xx) or timeout when calling <code>CheckpointDurableExecution / GetDurableExecutionState</code> APIs	Lambda automatically retries the invocation. The SDK replays from the last checkpoint.	Error payload size + 1 operation per retry
Throttling (429) or invalid checkpoint token when calling <code>CheckpointDurableExecution / GetDurableExecutionState</code> APIs	Lambda automatically retries the invocation with exponential backoff. The SDK replays from the last checkpoint.	Error payload size + 1 operation per retry
Client error (4xx, except 429 and invalid token) when calling <code>CheckpointDurableExecution / GetDurableExecutionState</code> APIs	The SDK marks the execution as FAILED. No automatic retry occurs because the error indicates a permanent issue.	Error payload size

Backend retries use exponential backoff and continue until the function succeeds or the execution timeout is reached. During replay, the SDK skips completed checkpoints and continues execution from the last successful operation, ensuring your function doesn't re-execute completed work.

Retry best practices

Follow these best practices when configuring retry strategies:

- **Configure explicit retry strategies** - Don't rely on default retry behavior in production. Configure explicit retry strategies with appropriate max attempts and backoff intervals for your use case.
- **Use conditional retries** - Implement `shouldRetry` logic to retry only transient errors (rate limits, timeouts) and fail fast on permanent errors (validation failures, not found).
- **Set appropriate max attempts** - Balance between resilience and execution time. Too many retries can delay failure detection, while too few can cause unnecessary failures.
- **Use exponential backoff** - Exponential backoff reduces load on downstream services and increases the likelihood of recovery from transient failures.
- **Wrap error-prone code in steps** - Code outside steps cannot be automatically retried. Wrap external API calls, database queries, and other error-prone operations in steps with retry strategies.
- **Monitor retry metrics** - Track step retry operations and execution failures in Amazon CloudWatch to identify patterns and optimize retry strategies.

Idempotency

Durable functions provide built-in idempotency for execution starts through execution names. When you provide an execution name, Lambda uses it to prevent duplicate executions and enable safe retries of invocation requests. Steps have at-least-once execution semantics by default—during replay, the SDK returns checkpointed results without re-executing completed steps, but your business logic must be idempotent to handle potential retries before completion.

Note

Lambda event source mappings (ESM) don't support idempotency at launch. Therefore, each invocation (including retries) starts a new durable execution. To ensure idempotent execution with event source mappings, either implement idempotency logic in your function code such as with [Powertools for AWS Lambda](#) or use a regular Lambda function as proxy (dispatcher) to invoke a durable function with an idempotency key (execution name parameter).

Execution names

You can provide an execution name when invoking a durable function. The execution name acts as an idempotency key, allowing you to safely retry invocation requests without creating duplicate executions. If you don't provide a name, Lambda generates a unique execution ID automatically.

Execution names must be unique within your account and region. When you invoke a function with an execution name that already exists, Lambda behavior depends on the existing execution's state and whether the payload matches.

Idempotency behavior

The following table describes how Lambda handles invocation requests based on whether you provide an execution name, the existing execution state, and whether the payload matches:

Scenario	Name provided?	Existing execution status	Payload identical?	Behavior
1	No	N/A	N/A	New execution started: Lambda generates a unique execution ID and starts a new execution
2	Yes	Never existed or retention expired	N/A	New execution started: Lambda starts a new execution with the provided name
3	Yes	Running	Yes	Idempotent start: Lambda returns the existing execution information without starting a duplicate . For synchronous invocations, this acts

Scenario	Name provided?	Existing execution status	Payload identical?	Behavior
				as a reattach to the running execution
4	Yes	Running	No	Error: Lambda returns <code>DurableExecutionAlreadyExists</code> error because an execution with this name is already running with different payload
5	Yes	Closed (succeeded, failed, stopped, or timed out)	Yes	Idempotent start: Lambda returns the existing execution information without starting a new execution. The closed execution result is returned
6	Yes	Closed (succeeded, failed, stopped, or timed out)	No	Error: Lambda returns <code>DurableExecutionAlreadyExists</code> error because an execution with this name already completed with different payload

Note

Scenarios 3 and 5 demonstrate idempotent behavior where Lambda safely handles duplicate invocation requests by returning existing execution information instead of creating duplicates.

Step idempotency

Steps have at-least-once execution semantics by default. When your function replays after a wait, callback, or failure, the SDK checks each step against the checkpoint log. For steps that already completed, the SDK returns the checkpointed result without re-executing the step logic. However, if a step fails or the function is interrupted before the step completes, the step may execute multiple times.

Your business logic wrapped in steps must be idempotent to handle potential retries. Use idempotency keys to ensure operations like payments or database writes execute only once, even if the step retries.

Example: Using idempotency keys in steps

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-js';
import { randomUUID } from 'crypto';

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    // Generate idempotency key once
    const idempotencyKey = await context.step('generate-key', async () => {
      return randomUUID();
    });

    // Use idempotency key in payment API to prevent duplicate charges
    const payment = await context.step('process-payment', async () => {
      return paymentAPI.charge({
        amount: event.amount,
        idempotencyKey: idempotencyKey
      });
    });

    return { statusCode: 200, payment };
  }
);
```

Python

```
from aws_durable_execution_sdk_python import durable_execution, DurableContext
import uuid

@durable_execution
def handler(event, context: DurableContext):
    # Generate idempotency key once
    idempotency_key = context.step(
        lambda _: str(uuid.uuid4()),
        name='generate-key'
    )

    # Use idempotency key in payment API to prevent duplicate charges
    payment = context.step(
        lambda _: payment_api.charge(
            amount=event['amount'],
            idempotency_key=idempotency_key
        ),
        name='process-payment'
    )

    return {'statusCode': 200, 'payment': payment}
```

You can configure steps to use at-most-once execution semantics by setting the execution mode to `AT_MOST_ONCE_PER_RETRY`. This ensures the step executes at most once per retry attempt, but may not execute at all if the function is interrupted before the step completes.

The SDK enforces deterministic replay by validating that step names and order match the checkpoint log during replay. If your code attempts to execute steps in a different order or with different names, the SDK throws a `NonDeterministicExecutionError`.

How replay works with completed steps:

1. First invocation: Function executes step A, creates checkpoint, then waits
2. Second invocation (after wait): Function replays from beginning, step A returns checkpointed result instantly without re-executing, then continues to step B

3. Third invocation (after another wait): Function replays from beginning, steps A and B return checkpointed results instantly, then continues to step C

This replay mechanism ensures that completed steps don't re-execute, but your business logic must still be idempotent to handle retries before completion.

Testing Lambda durable functions

AWS provides dedicated testing SDKs for durable functions that let you run and inspect executions both locally and in the cloud. Install the testing SDK for your language:

TypeScript

```
npm install --save-dev @aws/aws-durable-execution-sdk-js-testing
```

For complete documentation and examples, see the [TypeScript testing SDK](#) on GitHub.

Python

```
pip install aws-durable-execution-sdk-python-testing
```

For complete documentation and examples, see the [Python testing SDK](#) on GitHub.

The testing SDK provides two testing modes: local testing for fast unit tests, and cloud testing for integration tests against deployed functions.

Local testing

Local testing runs your durable functions in your development environment without requiring deployed resources. The test runner runs your function code directly and captures all operations for inspection.

Use local testing for unit tests, test-driven development, and CI/CD pipelines. Tests run locally without network latency or additional costs.

Example test:

TypeScript

```
import { withDurableExecution } from '@aws/aws-durable-execution-sdk-js';
import { DurableFunctionTestRunner } from '@aws/aws-durable-execution-sdk-js-testing';

const handler = withDurableExecution(async (event, context) => {
  const result = await context.step('calculate', async () => {
    return event.a + event.b;
  });
  return result;
});

test('addition works correctly', async () => {
  const runner = new DurableFunctionTestRunner({ handler });
  const result = await runner.run({ a: 5, b: 3 });

  expect(result.status).toBe('SUCCEEDED');
  expect(result.result).toBe(8);

  const step = result.getStep('calculate');
  expect(step.result).toBe(8);
});
```

Python

```
from aws_durable_execution_sdk_python import durable_execution, DurableContext
from aws_durable_execution_sdk_python_testing import DurableFunctionTestRunner
from aws_durable_execution_sdk_python.execution import InvocationStatus

@durable_execution
def handler(event: dict, context: DurableContext) -> int:
    result = context.step(lambda _: event["a"] + event["b"], name="calculate")
    return result

def test_addition():
    runner = DurableFunctionTestRunner(handler=handler)
    with runner:
```

```
result = runner.run(input={"a": 5, "b": 3}, timeout=10)

assert result.status is InvocationStatus.SUCCEEDED
assert result.result == 8

step = result.get_step("calculate")
assert step.result == 8
```

The test runner captures execution state including the final result, individual step results, wait operations, callbacks, and any errors. You can inspect operations by name or iterate through all operations to verify execution behavior.

Execution stores

The testing SDK uses execution stores to persist test execution data. By default, tests use an in-memory store that's fast and requires no cleanup. For debugging or analyzing execution history, you can use a filesystem store that saves executions as JSON files.

In-memory store (default):

The in-memory store keeps execution data in memory during test runs. Data is lost when tests complete, making it ideal for standard unit tests and CI/CD pipelines where you don't need to inspect executions after tests finish.

Filesystem store:

The filesystem store persists execution data to disk as JSON files. Each execution is saved in a separate file, making it easy to inspect execution history after tests complete. Use the filesystem store when debugging complex test failures or analyzing execution patterns over time.

Configure the store using environment variables:

```
# Use filesystem store
export AWS_DEX_STORE_TYPE=filesystem
export AWS_DEX_STORE_PATH=./test-executions

# Run tests
pytest tests/
```

Execution files are stored with sanitized names and contain the complete execution state including operations, checkpoints, and results. The filesystem store automatically creates the storage directory if it doesn't exist.

Cloud testing

Cloud testing invokes deployed durable functions in AWS and retrieves their execution history using the Lambda API. Use cloud testing to verify behavior in production-like environments with real AWS services and configurations.

Cloud testing requires a deployed function and AWS credentials with permissions to invoke functions and read execution history:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "lambda:InvokeFunction",
        "lambda:GetDurableExecution",
        "lambda:GetDurableExecutionHistory"
      ],
      "Resource": "arn:aws:lambda:region:account-id:function:function-name"
    }
  ]
}
```

Example cloud test:

TypeScript

```
import { DurableFunctionCloudTestRunner } from '@aws/aws-durable-execution-sdk-js-testing';

test('deployed function processes orders', async () => {
  const runner = new DurableFunctionCloudTestRunner({
    functionName: 'order-processor',
    region: 'us-east-1'
  });
});
```

```
});

const result = await runner.run({ orderId: 'order-123' });

expect(result.status).toBe('SUCCEEDED');
expect(result.result.status).toBe('completed');
});
```

Python

```
from aws_durable_execution_sdk_python_testing import (
    DurableFunctionCloudTestRunner,
    DurableFunctionCloudTestRunnerConfig
)

def test_deployed_function():
    config = DurableFunctionCloudTestRunnerConfig(
        function_name="order-processor",
        region="us-east-1"
    )
    runner = DurableFunctionCloudTestRunner(config=config)

    result = runner.run(input={"orderId": "order-123"})

    assert result.status is InvocationStatus.SUCCEEDED
    assert result.result["status"] == "completed"
```

Cloud tests invoke the actual deployed function and retrieve execution history from AWS. This lets you verify integration with other AWS services, validate performance characteristics, and test with production-like data and configurations.

What to test

Test durable functions by verifying execution outcomes, operation behavior, and error handling. Focus on business logic correctness rather than implementation details.

Verify execution results: Check that functions return the expected values for given inputs. Test both successful executions and error cases to ensure functions handle invalid input appropriately.

Inspect operation execution: Verify that steps, waits, and callbacks execute as expected.

Check step results to ensure intermediate operations produce correct values. Validate that wait operations are configured with appropriate timeouts and that callbacks are created with correct settings.

Test error handling: Verify functions fail correctly with descriptive error messages when given invalid input. Test retry behavior by simulating transient failures and confirming operations retry appropriately. Check that permanent failures don't trigger unnecessary retries.

Validate workflows: For multi-step workflows, verify operations execute in the correct order. Test conditional branching to ensure different execution paths work correctly. Validate parallel operations execute concurrently and produce expected results.

The SDK documentation repositories contain extensive examples of testing patterns including multi-step workflows, error scenarios, timeout handling, and polling patterns.

Testing strategy

Use local testing for unit tests during development and in CI/CD pipelines. Local tests run fast, don't require AWS credentials, and provide immediate feedback on code changes. Write local tests to verify business logic, error handling, and operation behavior.

Use cloud testing for integration tests before deploying to production. Cloud tests verify behavior with real AWS services and configurations, validate performance characteristics, and test end-to-end workflows. Run cloud tests in staging environments to catch integration issues before they reach production.

Mock external dependencies in local tests to isolate function logic and keep tests fast. Use cloud tests to verify actual integration with external services like databases, APIs, and other AWS services.

Write focused tests that verify one specific behavior. Use descriptive test names that explain what's being tested. Group related tests together and use test fixtures for common setup code. Keep tests simple and avoid complex test logic that's hard to understand.

Debugging failures

When tests fail, inspect the execution result to understand what went wrong. Check the execution status to see if the function succeeded, failed, or timed out. Read error messages to understand the failure cause.

Inspect individual operation results to find where behavior diverged from expectations. Check step results to see what values were produced. Verify operation ordering to confirm operations executed in the expected sequence. Count operations to ensure the right number of steps, waits, and callbacks were created.

Common issues include non-deterministic code that produces different results on replay, shared state through global variables that breaks during replay, and missing operations due to conditional logic errors. Use standard debuggers and logging to step through function code and track execution flow.

For cloud tests, inspect execution history in CloudWatch Logs to see detailed operation logs. Use tracing to track execution flow across services and identify bottlenecks.

Monitoring durable functions

You can monitor your durable functions using CloudWatch metrics, CloudWatch Logs, and tracing. Because durable functions can run for extended periods and span multiple function invocations, monitoring them requires understanding their unique execution patterns, including checkpoints, state transitions, and replay behavior.

CloudWatch metrics

Lambda automatically publishes metrics to CloudWatch at no additional charge. Durable functions provide additional metrics beyond standard Lambda metrics to help you monitor long-running workflows, state management, and resource utilization.

Durable execution metrics

Lambda emits the following metrics for durable executions:

Metric	Description
ApproximateRunningDurableExecutions	Number of durable executions in the RUNNING state
ApproximateRunningDurableExecutionsUtilization	Percentage of your account's maximum running durable executions quota currently in use

Metric	Description
DurableExecutionDuration	Elapsed wall-clock time in milliseconds that a durable execution remained in the RUNNING state
DurableExecutionStarted	Number of durable executions that started
DurableExecutionStopped	Number of durable executions stopped using the StopDurableExecution API
DurableExecutionSucceeded	Number of durable executions that completed successfully
DurableExecutionFailed	Number of durable executions that completed with a failure
DurableExecutionTimedOut	Number of durable executions that exceeded their configured execution timeout
DurableExecutionOperations	Cumulative number of operations performed within a durable execution (max: 3,000)
DurableExecutionStorageWrittenBytes	Cumulative amount of data in bytes persisted by a durable execution (max: 100 MB)

CloudWatch metrics

Lambda emits standard invocation, performance, and concurrency metrics for durable functions. Because a durable execution can span multiple function invocations as it progresses through checkpoints and replays, these metrics behave differently than for standard functions:

- **Invocations:** Counts each function invocation, including replays. A single durable execution can generate multiple invocation data points.
- **Duration:** Measures each function invocation separately. Use `DurableExecutionDuration` for total time taken by a single durable execution.
- **Errors:** Tracks function invocation failures. Use `DurableExecutionFailed` for execution-level failures.

For a complete list of standard Lambda metrics, see [Types of metrics for Lambda functions](#).

Creating CloudWatch alarms

Create CloudWatch alarms to notify you when metrics exceed thresholds. Common alarms include:

- `ApproximateRunningDurableExecutionsUtilization` exceeds 80% of your quota
- `DurableExecutionFailed` increases above a threshold
- `DurableExecutionTimedOut` indicates executions are timing out
- `DurableExecutionStorageWrittenBytes` approaches storage limits

For more information, [see Using CloudWatch alarms](#).

EventBridge events

Lambda publishes durable execution status change events to EventBridge. You can use these events to trigger workflows, send notifications, or track execution lifecycle changes across your durable functions.

Durable execution status change events

Lambda emits an event to EventBridge whenever a durable execution changes status. These events have the following characteristics:

- **Source:** `aws.lambda`
- **Detail type:** `Durable Execution Status Change`

Status change events are published for the following execution states:

- `RUNNING` - Execution started
- `SUCCEEDED` - Execution completed successfully
- `STOPPED` - Execution stopped using the `StopDurableExecution` API
- `FAILED` - Execution failed with an error
- `TIMED_OUT` - Execution exceeded the configured timeout

The following example shows a durable execution status change event:

```
{
  "version": "0",
  "id": "d019b03c-a8a3-9d58-85de-241e96206538",
  "detail-type": "Durable Execution Status Change",
  "source": "aws.lambda",
  "account": "123456789012",
  "time": "2025-11-20T13:08:22Z",
  "region": "us-east-1",
  "resources": [],
  "detail": {
    "durableExecutionArn": "arn:aws:lambda:us-east-1:123456789012:function:my-function:$LATEST/durable-execution/090c4189-b18b-4296-9d0c-cfd01dc3a122/9f7d84c9-ea3d-3ffc-b3e5-5ec51c34ffc9",
    "durableExecutionName": "order-123",
    "functionArn": "arn:aws:lambda:us-east-1:123456789012:function:my-function:2",
    "status": "RUNNING",
    "startTimestamp": "2025-11-20T13:08:22.345Z"
  }
}
```

For terminal states (SUCCEEDED, STOPPED, FAILED, TIMED_OUT), the event includes an `endTimeStamp` field indicating when the execution completed.

Creating EventBridge rules

Create rules to route durable execution status change events to targets like Amazon Simple Notification Service, Amazon Simple Queue Service, or other Lambda functions.

The following example creates a rule that matches all durable execution status changes:

```
{
  "source": ["aws.lambda"],
  "detail-type": ["Durable Execution Status Change"]
}
```

The following example creates a rule that matches only failed executions:

```
{
  "source": ["aws.lambda"],
  "detail-type": ["Durable Execution Status Change"],
  "detail": {
    "status": ["FAILED"]
  }
}
```

The following example creates a rule that matches status changes for a specific function:

```
{
  "source": ["aws.lambda"],
  "detail-type": ["Durable Execution Status Change"],
  "detail": {
    "functionArn": [{
      "prefix": "arn:aws:lambda:us-east-1:123456789012:function:my-function"
    }]
  }
}
```

For more information about creating rules, see [Amazon EventBridge tutorials](#) in the EventBridge User Guide.

AWS X-Ray tracing

You can enable X-Ray tracing on your durable functions. Lambda passes the X-Ray trace header to the durable execution, allowing you to trace requests across your workflow.

To enable X-Ray; tracing using the Lambda console, choose your function, then choose Configuration, Monitoring and operations tools, and turn on Active tracing under X-Ray.

To enable X-Ray tracing using the AWS CLI:

```
aws lambda update-function-configuration \
  --function-name my-durable-function \
  --tracing-config Mode=Active
```

To enable AWS X-Ray tracing using AWS SAM:

```
Resources:
  MyDurableFunction:
    Type: AWS::Serverless::Function
    Properties:
      Tracing: Active
      DurableConfig:
        ExecutionTimeout: 3600
```

For more information about X-Ray, [see the AWS X-Ray Developer Guide](#).

Best practices for Lambda durable functions

Durable functions use a replay-based execution model that requires different patterns than traditional Lambda functions. Follow these best practices to build reliable, cost-effective workflows.

Write deterministic code

During replay, your function runs from the beginning and must follow the same execution path as the original run. Code outside durable operations must be deterministic, producing the same results given the same inputs.

Wrap non-deterministic operations in steps:

- Random number generation and UUIDs
- Current time or timestamps
- External API calls and database queries
- File system operations

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-js';
import { randomUUID } from 'crypto';
```

```

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    // Generate transaction ID inside a step
    const transactionId = await context.step('generate-transaction-id', async () =>
    {
      return randomUUID();
    });

    // Use the same ID throughout execution, even during replay
    const payment = await context.step('process-payment', async () => {
      return processPayment(event.amount, transactionId);
    });

    return { statusCode: 200, transactionId, payment };
  }
);

```

Python

```

from aws_durable_execution_sdk_python import durable_execution, DurableContext
import uuid

@durable_execution
def handler(event, context: DurableContext):
    # Generate transaction ID inside a step
    transaction_id = context.step(
        lambda _: str(uuid.uuid4()),
        name='generate-transaction-id'
    )

    # Use the same ID throughout execution, even during replay
    payment = context.step(
        lambda _: process_payment(event['amount'], transaction_id),
        name='process-payment'
    )

    return {'statusCode': 200, 'transactionId': transaction_id, 'payment': payment}

```

Important

Don't use global variables or closures to share state between steps. Pass data through return values. Global state breaks during replay because steps return cached results but global variables reset.

Avoid closure mutations: Variables captured in closures can lose mutations during replay. Steps return cached results, but variable updates outside the step aren't replayed.

TypeScript

```
// # WRONG: Mutations lost on replay
export const handler = withDurableExecution(async (event, context) => {
  let total = 0;

  for (const item of items) {
    await context.step(async () => {
      total += item.price; // ## Mutation lost on replay!
      return saveItem(item);
    });
  }

  return { total }; // Inconsistent value!
});

// # CORRECT: Accumulate with return values
export const handler = withDurableExecution(async (event, context) => {
  let total = 0;

  for (const item of items) {
    total = await context.step(async () => {
      const newTotal = total + item.price;
      await saveItem(item);
      return newTotal; // Return updated value
    });
  }

  return { total }; // Consistent!
});

// # EVEN BETTER: Use map for parallel processing
export const handler = withDurableExecution(async (event, context) => {
  const results = await context.map(
    items,
```

```

    async (ctx, item) => {
      await ctx.step(async () => saveItem(item));
      return item.price;
    }
  );

  const total = results.getResults().reduce((sum, price) => sum + price, 0);
  return { total };
});

```

Python

```

# # WRONG: Mutations lost on replay
@durable_execution
def handler(event, context: DurableContext):
    total = 0

    for item in items:
        context.step(
            lambda _: save_item_and_mutate(item, total), # ## Mutation lost on
replay!
            name=f'save-item-{item["id"]}'
        )

    return {'total': total} # Inconsistent value!

# # CORRECT: Accumulate with return values
@durable_execution
def handler(event, context: DurableContext):
    total = 0

    for item in items:
        total = context.step(
            lambda _: save_item_and_return_total(item, total),
            name=f'save-item-{item["id"]}'
        )

    return {'total': total} # Consistent!

# # EVEN BETTER: Use map for parallel processing
@durable_execution

```

```
def handler(event, context: DurableContext):
    def process_item(ctx, item):
        ctx.step(lambda _: save_item(item))
        return item['price']

    results = context.map(items, process_item)
    total = sum(results.get_results())

    return {'total': total}
```

Design for idempotency

Operations may execute multiple times due to retries or replay. Non-idempotent operations cause duplicate side effects like charging customers twice or sending multiple emails.

Use idempotency tokens: Generate tokens inside steps and include them with external API calls to prevent duplicate operations.

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-
js';

export const handler = withDurableExecution(
  async (event: any, context: DurableContext) => {
    // Generate idempotency token once
    const idempotencyToken = await context.step('generate-idempotency-token', async
    () => {
      return crypto.randomUUID();
    });

    // Use token to prevent duplicate charges
    const charge = await context.step('charge-payment', async () => {
      return paymentService.charge({
        amount: event.amount,
        cardToken: event.cardToken,
        idempotencyKey: idempotencyToken
      });
    });
  });
```

```

        return { statusCode: 200, charge };
    }
};

```

Python

```

from aws_durable_execution_sdk_python import durable_execution, DurableContext
import uuid

@durable_execution
def handler(event, context: DurableContext):
    # Generate idempotency token once
    idempotency_token = context.step(
        lambda _: str(uuid.uuid4()),
        name='generate-idempotency-token'
    )

    # Use token to prevent duplicate charges
    def charge_payment(_):
        return payment_service.charge(
            amount=event['amount'],
            card_token=event['cardToken'],
            idempotency_key=idempotency_token
        )

    charge = context.step(charge_payment, name='charge-payment')

    return {'statusCode': 200, 'charge': charge}

```

Use at-most-once semantics: For critical operations that must never duplicate (financial transactions, inventory deductions), configure at-most-once execution mode.

TypeScript

```

// Critical operation that must not duplicate
await context.step('deduct-inventory', async () => {
    return inventoryService.deduct(event.productId, event.quantity);
}, {

```

```
    executionMode: 'AT_MOST_ONCE_PER_RETRY'  
  });
```

Python

```
# Critical operation that must not duplicate  
context.step(  
    lambda _: inventory_service.deduct(event['productId'], event['quantity']),  
    name='deduct-inventory',  
    config=StepConfig(execution_mode='AT_MOST_ONCE_PER_RETRY')  
)
```

Database idempotency: Use check-before-write patterns, conditional updates, or upsert operations to prevent duplicate records.

Manage state efficiently

Every checkpoint saves state to persistent storage. Large state objects increase costs, slow checkpointing, and impact performance. Store only essential workflow coordination data.

Keep state minimal:

- Store IDs and references, not full objects
- Fetch detailed data within steps as needed
- Use Amazon S3 or DynamoDB for large data, pass references in state
- Avoid passing large payloads between steps

TypeScript

```
import { withDurableExecution, DurableContext } from '@aws/durable-execution-sdk-  
js';  
  
export const handler = withDurableExecution(  
    async (event: any, context: DurableContext) => {
```

```
// Store only the order ID, not the full order object
const orderId = event.orderId;

// Fetch data within each step as needed
await context.step('validate-order', async () => {
  const order = await orderService.getOrder(orderId);
  return validateOrder(order);
});

await context.step('process-payment', async () => {
  const order = await orderService.getOrder(orderId);
  return processPayment(order);
});

return { statusCode: 200, orderId };
}
);
```

Python

```
from aws_durable_execution_sdk_python import durable_execution, DurableContext

@durable_execution
def handler(event, context: DurableContext):
    # Store only the order ID, not the full order object
    order_id = event['orderId']

    # Fetch data within each step as needed
    context.step(
        lambda _: validate_order(order_service.get_order(order_id)),
        name='validate-order'
    )

    context.step(
        lambda _: process_payment(order_service.get_order(order_id)),
        name='process-payment'
    )

    return {'statusCode': 200, 'orderId': order_id}
```

Design effective steps

Steps are the fundamental unit of work in durable functions. Well-designed steps make workflows easier to understand, debug, and maintain.

Step design principles:

- **Use descriptive names** - Names like `validate-order` instead of `step1` make logs and errors easier to understand
- **Keep names static** - Don't use dynamic names with timestamps or random values. Step names must be deterministic for replay
- **Balance granularity** - Break complex operations into focused steps, but avoid excessive tiny steps that increase checkpoint overhead
- **Group related operations** - Operations that should succeed or fail together belong in the same step

Use wait operations efficiently

Wait operations suspend execution without consuming resources or incurring costs. Use them instead of keeping Lambda running.

Time-based waits: Use `context.wait()` for delays instead of `setTimeout` or `sleep`.

External callbacks: Use `context.waitForCallback()` when waiting for external systems. Always set timeouts to prevent indefinite waits.

Polling: Use `context.waitForCondition()` with exponential backoff to poll external services without overwhelming them.

TypeScript

```
// Wait 24 hours without cost
await context.wait({ seconds: 86400 });

// Wait for external callback with timeout
const result = await context.waitForCallback(
  'external-job',
  async (callbackId) => {
    await externalService.submitJob({
```

```
        data: event.data,
        webhookUrl: `https://api.example.com/callbacks/${callbackId}`
    });
},
{ timeout: { seconds: 3600 } }
);
```

Python

```
# Wait 24 hours without cost
context.wait(86400)

# Wait for external callback with timeout
result = context.wait_for_callback(
    lambda callback_id: external_service.submit_job(
        data=event['data'],
        webhook_url=f'https://api.example.com/callbacks/{callback_id}'
    ),
    name='external-job',
    config=WaitForCallbackConfig(timeout_seconds=3600)
)
```

Additional considerations

Error handling: Retry transient failures like network timeouts and rate limits. Don't retry permanent failures like invalid input or authentication errors. Configure retry strategies with appropriate max attempts and backoff rates. For detailed examples, see [Error handling and retries](#).

Performance: Minimize checkpoint size by storing references instead of full payloads. Use `context.parallel()` and `context.map()` to execute independent operations concurrently. Batch related operations to reduce checkpoint overhead.

Versioning: Invoke functions with version numbers or aliases to pin executions to specific code versions. Ensure new code versions can handle state from older versions. Don't rename steps or change their behavior in ways that break replay.

Serialization: Use JSON-compatible types for operation inputs and results. Convert dates to ISO strings and custom objects to plain objects before passing them to durable operations.

Monitoring: Enable structured logging with execution IDs and step names. Set up CloudWatch alarms for error rates and execution duration. Use tracing to identify bottlenecks. For detailed guidance, see [Monitoring and debugging](#).

Testing: Test happy path, error handling, and replay behavior. Test timeout scenarios for callbacks and waits. Use local testing to reduce iteration time. For detailed guidance, see [Testing durable functions](#).

Common mistakes to avoid: Don't nest `context.step()` calls, use child contexts instead. Wrap non-deterministic operations in steps. Always set timeouts for callbacks. Balance step granularity with checkpoint overhead. Store references instead of large objects in state.

Lambda Managed Instances

Lambda Managed Instances enables you to run Lambda functions on your current-generation Amazon EC2 instances, including Graviton4, network-optimized instances, and other specialized compute options, without managing instance lifecycles, operating system and language runtime patching, routing, load balancing, or scaling policies. With Lambda Managed Instances, you benefit from EC2 pricing advantages, including EC2 Savings Plans and Reserved Instances.

For a list of supported instance types, go to the [AWS Lambda Pricing](#) page and select your AWS Region.

Key capabilities

Lambda Managed Instances provides the following capabilities:

- **Choose suitable instances** - Select [appropriate instances](#) based on performance and cost requirements, including access to the latest CPUs like Graviton4, configurable memory-CPU ratios, and high-bandwidth networking.
- **Automatic provisioning** - AWS automatically provisions suitable instances and spins up function execution environments.
- **Dynamic scaling** - Instances scale dynamically based on your function traffic patterns.
- **Fully managed experience** - AWS handles infrastructure management, scaling, patching, and routing, with the same extensive event-source integrations you're familiar with.

When to use Lambda Managed Instances

Consider Lambda Managed Instances for the following use cases:

- **High volume-predictable workloads** - Best suited for steady-state workloads without unexpected traffic spikes. Lambda Managed Instances scale to handle traffic doubling within five minutes by default.
- **Performance-critical applications** - Access to latest CPUs, varying memory-CPU ratios, and high network throughput
- **Regulatory requirements** - Granular governance needs with control over VPC and instance placement

- **Variety of applications** - Event-driven applications, media/data processing, web applications, and legacy workloads migrating to serverless

How it works

Lambda Managed Instances uses capacity providers as the foundation for running your functions:

1. **Create a capacity provider** - Define where your functions run by specifying VPC configuration and optionally, instance requirements, and scaling configuration
2. **Create your function** - Create Lambda functions as usual and attach them to a capacity provider
3. **Publish a function version** - Function versions become active on capacity provider instances once published

When you publish a function version with a capacity provider, Lambda launches Managed Instances in your account. It launches three instances by default for AZ resiliency and starts three execution environments before marking your function version **ACTIVE**. If you attach a function to an existing capacity provider that is already running other functions, Lambda may not spin up new instances if the available instances already have capacity to accommodate the new function's execution environments.

Concurrency model

Lambda Managed Instances support multi-concurrent invocations, where one execution environment can handle multiple invocations at the same time. This differs from the Lambda (default) compute type, which provides a single concurrency model where one execution environment can run a maximum of one invoke at a time. Multi-concurrency yields better utilization of your underlying EC2 instances and is especially beneficial for IO-heavy applications like web services or batch jobs. This change in execution model means that thread safety, state management, and context isolation must be handled differently depending on the runtime.

Tenancy and isolation

Lambda (default) compute type is multi-tenant, making use of Firecracker microVM technology to provide isolation between execution environments running on shared Lambda fleets. Lambda Managed Instances run in your account, providing the latest EC2 hardware and pricing options.

Managed Instances use containers running on EC2 Nitro instances to provide isolation rather than Firecracker. Capacity providers serve as the security boundary for Lambda functions. Functions execute in containers within instances.

Understanding managed instances

Lambda Managed Instances functions run on EC2 managed instances in your account. These instances are fully managed by Lambda, which means you have restricted permissions on them compared to standard EC2 instances. You can identify Lambda Managed Instances in your account by:

- The presence of the `Operator` field in `EC2 DescribeInstances` output
- The `aws:lambda:capacity-provider` tag on the instance

You cannot perform standard EC2 operations directly on these instances, such as terminating them manually. To destroy managed instances, delete the associated capacity provider. Lambda will then terminate the instances as part of the capacity provider deletion process.

Pricing

Lambda Managed Instances uses EC2-based pricing with a 15% management fee on top of the EC2 instance cost. This pricing model supports EC2 Savings Plans, Reserved Instances and any other pricing discounts applied to your EC2 usage. Refer to pricing page for additional details: <https://aws.amazon.com/lambda/pricing/>

Important: EC2 pricing discounts only apply to the underlying EC2 compute, not to the management fee.

How Lambda Managed Instances differs from the Lambda (default) compute type

Lambda Managed Instances changes how Lambda processes requests compared to Lambda (default).

Key differences:

	Lambda (default)	Lambda Managed Instances
Concurrency model	Single concurrency model where one execution environment can support a maximum of one invocation at a time	Multi-concurrent invocations where one execution environment can handle multiple invocations simultaneously, increasing throughput especially for IO-heavy applications
Tenancy and isolation	Multi-tenant, using Firecracker microVM technology to provide isolation between execution environments running on shared Lambda fleets	Run in your account, using EC2 Nitro to provide isolation. Capacity providers serve as the security boundary, with functions executing in containers within instances
Pricing model	Per-request duration pricing	Instance-based pricing with EC2 pricing models, including On-Demand and Reserved Instances , and savings options such as Compute Savings Plans
Scaling behavior	Scales when there is no free execution environment to handle an incoming invocation (cold start). Scales to zero without traffic	Scales asynchronously based on CPU resource utilization only, without cold starts. Scales to minimum execution environments configured without traffic
Best suited for	Functions with bursty traffic that can handle some cold-start time, or applications without sustained load that benefit from scale to zero	High volume predictable traffic functions when you want the flexibility, pricing plans, and hardware options of EC2

Next steps

- Learn about [capacity providers for Lambda Managed Instances](#)

- Understand [scaling for Lambda Managed Instances](#)
- Review runtime-specific guides for [Java](#), [Node.js](#), and [Python](#)
- Configure [VPC connectivity for your capacity providers](#)
- Understand [security and permissions for Lambda Managed Instances](#)

Getting started with Lambda Managed Instances

Creating a Lambda Managed Instance function (console)

You can use the Lambda console to create a Managed Instance function that runs on Amazon EC2 instances managed by a capacity provider.

Important: Before creating a Managed Instance function, you must first create a capacity provider. These functions require a capacity provider to define the Amazon EC2 infrastructure that will run your functions.

To create a Lambda Managed Instance function (console)

1. Open the Lambda console.
2. Choose **Capacity providers** from the left navigation pane.
3. Choose **Create capacity provider**.
4. In the **Capacity provider settings** section, enter a name for your capacity provider.
5. Select VPC and permissions for your capacity provider. You can either use an existing or create a new one. For information about creating the required operator role, see [Lambda Operator role for Lambda Managed Instances](#).
6. Expand **Advanced settings**.
7. Define your **Instance requirements** by choosing the processor architecture and instance types.
8. Under **Auto scaling**, specify the maximum number of EC2 vCPUs for your capacity provider. You can also choose **Manual instance scaling mode** to set your own scaling value for precise control.
9. Choose **Create capacity provider** to create a new one.
10. Next, choose **Create function**.
11. Select **Author from scratch**.
12. In the **Basic information** pane, provide a **Function name**.
13. For **Runtime**, choose any of the supported Runtimes.

- 14 Choose the **Architecture** for your function (same as the one you selected for capacity provider).
By default, **x86_64**.
- 15 Under **Permissions**, ensure you have permission for the chosen **Execution role**. Otherwise, you can create a new role.
- 16 Under **Additional configurations**, pick the **Compute type** as **Lambda Managed Instances**.
- 17 Capacity provider ARN of the capacity provider you created in the previous steps should be pre-selected.
- 18 Choose **Memory size** and **Execution environment memory (GiB) per vCPU ratio**.
- 19 Choose **Create function**.

Your Lambda Managed Instance function is created and will provision capacity on your specified capacity provider. Function creation typically takes several minutes. Once complete, you can edit your function code and run your first test.

Creating a Lambda Managed Instance function (AWS CLI)

Prerequisites

Before you begin, make sure you have the following:

- **AWS CLI** – Install and configure the AWS CLI. For more information, see [Installing or updating the latest version of the AWS CLI](#).
- **IAM permissions** – Your IAM user or role must have permissions to create Lambda functions, capacity providers, and pass IAM roles. Note that you'll also need `iam:CreateServiceLinkedRole` if it's the first time creating a capacity provider in the account or if the Service Linked Role (SLR) was deleted.

Step 1: Create the required IAM roles

Lambda Managed Instances require two IAM roles: an execution role for your function and an operator role for the capacity provider. The operator role allows Lambda to launch, terminate, and monitor Amazon EC2 instances on your behalf. The function execution role grants the function permissions to access other AWS services and resources.

To create the Lambda execution role

1. Create a trust policy document that allows Lambda to assume the role:

```
cat > lambda-trust-policy.json << 'EOF'
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
EOF
```

2. Create the execution role:

```
aws iam create-role \
  --role-name MyLambdaExecutionRole \
  --assume-role-policy-document file://lambda-trust-policy.json
```

3. Attach the basic execution policy:

```
aws iam attach-role-policy \
  --role-name MyLambdaExecutionRole \
  --policy-arn arn:aws:iam::aws:policy/service-role/AWSLambdaBasicExecutionRole
```

To create the capacity provider operator role

1. Create a trust policy document that allows Lambda to assume the operator role:

```
cat > operator-trust-policy.json << 'EOF'
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
```

```
}  
]  
}  
EOF
```

2. Create the operator role:

```
aws iam create-role \  
  --role-name MyCapacityProviderOperatorRole \  
  --assume-role-policy-document file://operator-trust-policy.json
```

3. Attach the required EC2 permissions policy:

```
aws iam attach-role-policy \  
  --role-name MyCapacityProviderOperatorRole \  
  --policy-arn arn:aws:iam::aws:policy/AWSLambdaManagedEC2ResourceOperator
```

Step 2: Set up VPC resources

Lambda Managed Instances run in your VPC and require a subnet and security group.

To create VPC resources

1. Create a VPC:

```
VPC_ID=$(aws ec2 create-vpc \  
  --cidr-block 10.0.0.0/16 \  
  --query 'Vpc.VpcId' \  
  --output text)
```

2. Create a subnet:

```
SUBNET_ID=$(aws ec2 create-subnet \  
  --vpc-id $VPC_ID \  
  --cidr-block 10.0.1.0/24 \  
  --query 'Subnet.SubnetId' \  
  --output text)
```

3. Create a security group:

```
SECURITY_GROUP_ID=$(aws ec2 create-security-group \  
  --group-name my-capacity-provider-sg \  
  --vpc-id $VPC_ID)
```

```
--description "Security group for Lambda Managed Instances" \  
--vpc-id $VPC_ID \  
--query 'GroupId' \  
--output text)
```

Note: Your Lambda Managed Instances functions require VPC configuration to access resources outside the VPC and to transmit telemetry data to CloudWatch Logs and X-Ray. For configuration details, see [Networking for Lambda Managed Instances](#).

Step 3: Create a capacity provider

A capacity provider manages the EC2 instances that run your Lambda functions.

To create a capacity provider

```
ACCOUNT_ID=$(aws sts get-caller-identity --query Account --output text)  
  
aws lambda create-capacity-provider \  
  --capacity-provider-name my-capacity-provider \  
  --vpc-config SubnetIds=[$SUBNET_ID],SecurityGroupIds=[$SECURITY_GROUP_ID] \  
  --permissions-config CapacityProviderOperatorRoleArn=arn:aws:iam:${ACCOUNT_ID}:role/  
MyCapacityProviderOperatorRole \  
  --instance-requirements Architectures=[x86_64] \  
  --capacity-provider-scaling-config MaxVCpuCount=30
```

This command creates a capacity provider with the following configuration:

- **VPC configuration** – Specifies the subnet and security group for the EC2 instances
- **Permissions** – Defines the IAM role that Lambda uses to manage EC2 instances
- **Instance requirements** – Specifies the x86_64 architecture
- **Scaling configuration** – Sets a maximum of 30 vCPUs for the capacity provider

Step 4: Create a Lambda function with inline code

To create a function with inline code

1. First, create a simple Python function and package it inline:

```
# Create a temporary directory for the function code  
mkdir -p /tmp/my-lambda-function
```

```
cd /tmp/my-lambda-function

# Create a simple Python handler
cat > lambda_function.py << 'EOF'
import json

def lambda_handler(event, context):
    return {
        'statusCode': 200,
        'body': json.dumps({
            'message': 'Hello from Lambda Managed Instances!',
            'event': event
        })
    }
EOF

# Create a ZIP file
zip function.zip lambda_function.py
```

2. Create the Lambda function using the inline ZIP file:

```
ACCOUNT_ID=$(aws sts get-caller-identity --query Account --output text)
REGION=$(aws configure get region)

aws lambda create-function \
  --function-name my-managed-instance-function \
  --package-type Zip \
  --runtime python3.13 \
  --handler lambda_function.lambda_handler \
  --zip-file fileb:///tmp/my-lambda-function/function.zip \
  --role arn:aws:iam::${ACCOUNT_ID}:role/MyLambdaExecutionRole \
  --architectures x86_64 \
  --memory-size 2048 \
  --ephemeral-storage Size=512 \
  --capacity-provider-config
LambdaManagedInstancesCapacityProviderConfig={CapacityProviderArn=arn:aws:lambda:
${REGION}:${ACCOUNT_ID}:capacity-provider:my-capacity-provider}
```

The function is created with:

- **Runtime** – Python 3.13
- **Handler** – The `lambda_handler` function in `lambda_function.py`
- **Memory** – 2048 MB

- **Ephemeral storage** – 512 MB
- **Capacity provider** – Links to the capacity provider you created

Step 5: Publish a function version

To run your function on Lambda Managed Instances, you must publish a version.

To publish a function version

```
aws lambda publish-version \  
  --function-name my-managed-instance-function
```

This command publishes version 1 of your function and deploys it to the capacity provider.

Step 6: Invoke your function

After publishing, you can invoke your function.

To invoke your function

```
aws lambda invoke \  
  --function-name my-managed-instance-function:1 \  
  --payload '{"name": "World"}' \  
  response.json  
  
# View the response  
cat response.json
```

The function runs on the EC2 instances managed by your capacity provider and returns a response.

Clean up

To avoid incurring charges, delete the resources you created:

1. Delete the function:

```
aws lambda delete-function --function-name my-managed-instance-function
```

2. Delete the capacity provider:

```
aws lambda delete-capacity-provider --capacity-provider-name my-capacity-provider
```

3. Delete the VPC resources:

```
aws ec2 delete-security-group --group-id $SECURITY_GROUP_ID
aws ec2 delete-subnet --subnet-id $SUBNET_ID
aws ec2 delete-vpc --vpc-id $VPC_ID
```

4. Delete the IAM roles:

```
aws iam detach-role-policy \
  --role-name MyLambdaExecutionRole \
  --policy-arn arn:aws:iam::aws:policy/service-role/AWSLambdaBasicExecutionRole
aws iam detach-role-policy \
  --role-name MyCapacityProviderOperatorRole \
  --policy-arn arn:aws:iam::aws:policy/AWSLambdaManagedEC2ResourceOperator

aws iam delete-role --role-name MyLambdaExecutionRole
aws iam delete-role --role-name MyCapacityProviderOperatorRole
```

Core concepts

Lambda Managed Instances introduces several core concepts that differ from traditional Lambda functions. Understanding these concepts is essential for effectively deploying and managing your functions on EC2 infrastructure.

Capacity providers form the foundation of Lambda Managed Instances. A capacity provider defines the compute infrastructure where your functions execute, including VPC configuration, instance requirements, and scaling policies. Capacity providers also serve as the security boundary for your functions, meaning all functions assigned to the same capacity provider must be mutually trusted.

Scaling behavior differs significantly from traditional Lambda functions. Instead of scaling on-demand when invocations arrive, Managed Instances scale asynchronously based on CPU resource utilization. This approach eliminates cold starts but requires planning for traffic growth. If your traffic more than doubles within 5 minutes, you may experience throttles as Lambda scales up capacity to meet demand.

Security and permissions require careful consideration. You need operator role permissions to allow Lambda to manage EC2 resources in your capacity providers. Additionally, users need the

`lambda:PassCapacityProvider` permission to assign functions to capacity providers, acting as a security gate to control which functions can run on specific infrastructure.

Multi-concurrent execution is a key characteristic of Managed Instances. Each execution environment can handle multiple invocations simultaneously, maximizing resource utilization for IO-heavy applications. This differs from traditional Lambda where each environment processes one request at a time. This execution model requires attention to thread safety, state management, and context isolation depending on your runtime.

The following sections provide detailed information about each core concept.

Capacity providers

A capacity provider is the foundation for running Lambda Managed Instances. It acts as the security boundary for your functions and defines the compute resources that Lambda will provision and manage on your behalf.

When you create a capacity provider, you specify:

- **VPC configuration** - The subnets and security groups where instances will run
- **Permissions** - IAM roles for Lambda to manage EC2 resources
- **Instance requirements** (optional) - Architecture and [instance type](#) preferences
- **Scaling configuration** (optional) - How Lambda scales your instances

Understanding capacity providers as security boundary

Capacity providers serve as the security boundary for Lambda functions within your VPC, replacing Firecracker-based isolation. Functions execute in containers within instances, but containers do not provide strong security isolation between functions, unlike Firecracker microVMs.

Key security concepts:

- **Capacity Provider:** The security boundary that defines trust levels for Lambda functions
- **Container Isolation:** Containers are NOT a security provider - do not rely on them for security between untrusted workloads
- **Trust Separation:** Separate workloads that are not mutually trusted by using different capacity providers

Creating a capacity provider

You can create a capacity provider using the AWS CLI, AWS Management Console, or AWS SDKs.

Using AWS CLI:

```
aws lambda create-capacity-provider \
  --capacity-provider-name my-capacity-provider \
  --vpc-config
SubnetIds=subnet-12345,subnet-67890,subnet-11111,SecurityGroupIds=sg-12345 \
  --permissions-config CapacityProviderOperatorRoleArn=arn:aws:iam::123456789012:role/
MyOperatorRole \
  --instance-requirements Architectures=x86_64 \
  --capacity-provider-scaling-config ScalingMode=Auto
```

Required parameters

CapacityProviderName

- A unique name for your capacity provider
- Must be unique within your AWS account

VpcConfig

- **SubnetIds** (required): At least one subnet, maximum of 16. Use subnets across multiple Availability Zones for resiliency
- **SecurityGroupIds** (optional): Security groups for your instances. Defaults to the VPC default security group if not specified

PermissionsConfig

- **CapacityProviderOperatorRoleArn** (required): IAM role that allows Lambda to manage EC2 resources in your capacity provider

Optional parameters

InstanceRequirements

Specify the architecture and [instance types](#) for your capacity provider:

- **Architectures:** Choose `x86_64` or `arm64`. Default is `x86_64`
- **AllowedInstanceTypes:** Specify allowed instance types. Example: `m5.xlarge`
- **ExcludedInstanceTypes:** Specify excluded instance types using wildcards. You can specify only one of `AllowedInstanceTypes` or `ExcludedInstanceTypes`

By default, Lambda chooses the best instance types for your workload. We recommend letting Lambda Managed Instances choose instance types for you, as restricting the number of possible instance types may result in lower availability.

CapacityProviderScalingConfig

Configure how Lambda scales your instances:

- **ScalingMode:** Set to `Auto` for automatic scaling or `Manual` for manual control. Default is `Auto`
- **MaxVCpuCount:** Maximum number of vCPUs for the capacity provider. Default is 400.
- **ScalingPolicies:** Define target tracking scaling policies for CPU and memory utilization

KmsKeyArn

Specify a AWS KMS key for EBS encryption. Defaults to AWS managed key if not specified.

Tags

Add tags to organize and manage your capacity providers.

Managing capacity providers

Updating a capacity provider

You can update certain properties of a capacity provider using the `UpdateCapacityProvider` API.

```
aws lambda update-capacity-provider \  
  --capacity-provider-name my-capacity-provider \  
  --capacity-provider-scaling-config ScalingMode=Auto
```

Deleting a capacity provider

You can delete a capacity provider when it's no longer needed using the `DeleteCapacityProvider` API.

```
aws lambda delete-capacity-provider \  
  --capacity-provider-name my-capacity-provider
```

Note: You cannot delete a capacity provider that has function versions attached to it.

Viewing capacity provider details

Retrieve information about a capacity provider using the `GetCapacityProvider` API.

```
aws lambda get-capacity-provider \  
  --capacity-provider-name my-capacity-provider
```

Capacity provider states

A capacity provider can be in one of the following states:

- **Pending:** The capacity provider is being created
- **Active:** The capacity provider is ready to use
- **Failed:** The capacity provider creation failed
- **Deleting:** The capacity provider is being deleted

Quotas

- **Maximum capacity providers per account:** 1,000
- **Maximum function versions per capacity provider:** 100 (cannot be increased)

Best practices

1. **Separate by trust level:** Create different capacity providers for workloads with different security requirements
2. **Use descriptive names:** Name capacity providers to clearly indicate their intended use and trust level (e.g., `production-trusted`, `dev-sandbox`)
3. **Use multiple Availability Zones:** Specify subnets across multiple AZs for high availability
4. **Let Lambda choose instance types:** Unless you have specific hardware requirements, allow Lambda to select the best instance types for optimal availability

5. **Monitor usage:** Use AWS CloudTrail to monitor capacity provider assignments and access patterns

Next steps

- Learn about [scaling Lambda Managed Instances](#)
- Understand [security and permissions for Lambda Managed Instances](#)
- Configure [VPC connectivity for your capacity providers](#)
- Review runtime-specific guides for [Java](#), [Node.js](#), and [Python](#)

Scaling Lambda Managed Instances

Lambda Managed Instances does not scale when invocations arrive and does not support cold starts. Instead, it scales asynchronously using resource consumption signals. Managed Instances currently scales based on CPU resource utilization and multi-concurrency saturation.

Key differences:

- **Lambda (default):** Scales when there is no free execution environment to handle an incoming invocation (cold start)
- **Lambda Managed Instances:** Scales asynchronously based on CPU resource utilization and multi-concurrency saturation of execution environments

If your traffic more than doubles within 5 minutes, you may see throttles as Lambda scales up instances and execution environments to meet demand.

The scaling lifecycle

Lambda Managed Instances uses a distributed architecture to manage scaling:

Components:

- **Managed Instances** - Run in your account in the subnets you provide
- **Router and Scaler** - Shared Lambda components that route invocations and manage scaling
- **Lambda Agent** - Runs on each Managed Instance to manage execution environment lifecycle and monitor resource consumption

How it works:

1. When you publish a function version with a capacity provider, Lambda launches Managed Instances in your account. It launches three by default for AZ resiliency and starts three execution environments before marking your function version ACTIVE.
2. Each Managed Instance can run execution environments for multiple functions mapped to the same capacity provider.
3. As traffic flows into your application, execution environments consume resources. The Lambda Agent notifies the Scaler, which decides whether to scale new execution environments or Managed Instances.
4. If Router attempts to send an invocation to an execution environment with high resource consumption, the Lambda Agent on that instance notifies it to retry on another.
5. As traffic decreases, the Lambda Agent notifies Scaler, which makes a decision to scale down execution environments and scale in Managed Instances.

Adjusting scaling behavior

You can customize the scaling behavior of Managed Instances through four controls:

Function level controls

1. Function memory and vCPUs

Choose the memory size and vCPU allocation for your function. The smallest supported function size is 2GB and 1vCPU.

Considerations:

- Pick a memory and vCPU setting that will support multi-concurrent executions of your function
- You cannot configure a function with less than 1 vCPU because functions running on Managed Instances should support multi-concurrent workloads
- You cannot choose less than 2GB because this matches the 2 to 1 memory to vCPU ratio of c instances, which have the lowest ratio
- For Python applications, you may need to choose a higher ratio of memory to vCPUs, such as 4 to 1 or 8 to 1, because of the way Python handles multi-concurrency
- If you are running CPU-intensive operations or perform little IO, you should choose more than one vCPU

2. Maximum concurrency

Set the maximum concurrency per execution environment.

Default behavior: Lambda chooses sensible defaults that balance resource consumption and throughput that work for a wide variety of applications.

Adjustment guidelines:

- **Increase concurrency:** If your function invocations use very little CPU, you can increase maximum concurrency up to a maximum of 64 per vCPU
- **Decrease concurrency:** If your application consumes a large amount of memory and very little CPU, you can reduce your maximum concurrency

Important: Since Lambda Managed Instances are meant for multi-concurrent applications, execution environments with very low concurrency may experience throttles when scaling.

Capacity provider level controls

3. Target resource utilization

Choose your own target for CPU utilization consumption.

Default behavior: Lambda maintains enough headroom for your traffic to double within 5 minutes without throttles.

Optimization options:

- If your workload is very steady or if your application is not sensitive to throttles, you may set the target to a high level to achieve higher utilization and lower costs
- If you want to maintain headroom for bursts of traffic, you can set resource targets to a low level, which will require more capacity

4. Instance type selection

Set allowed or excluded instance types.

Default behavior: Lambda chooses the best instance types for your workload. We recommend letting Lambda Managed Instances choose instance types for you, as restricting the number of possible instance types may result in lower availability.

Custom configuration:

- **Specific hardware requirements:** Set allowed instance types to a list of compatible instances. For example, if you have an application that requires high network bandwidth, you can select several n instance types
- **Cost optimization:** For testing or development environments, you might choose smaller instance types, like m7a.large instance types

Next steps

- Learn about [capacity providers for Lambda Managed Instances](#)
- Review runtime-specific guides for handling multi-concurrency
- Configure [VPC connectivity for your capacity providers](#)
- Monitor scaling metrics to optimize scaling behavior

Security and permissions

Lambda Managed Instances use **capacity providers as trust boundaries**. Functions execute in containers within these instances, but containers do not provide security isolation between workloads. All functions assigned to the same capacity provider must be mutually trusted.

Key Security Concepts

- **Capacity Provider:** The security boundary that defines trust levels for Lambda functions
- **Container Isolation:** Containers are not a security boundary - do not rely on them for security between untrusted workloads
- **Trust Separation:** Separate workloads that are not mutually trusted by using different capacity providers

Required Permissions

PassCapacityProvider Action

Users need the `lambda:PassCapacityProvider` permission to assign functions to capacity providers. This permission acts as a security gate, ensuring only authorized users can place functions in specific capacity providers.

Account administrators control which functions can use specific capacity providers through the `lambda:PassCapacityProvider` IAM action. This action is required when:

- Creating functions that use Lambda Managed Instances
- Updating function configurations to use a capacity provider
- Deploying functions via infrastructure as code

Example IAM Policy

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": "lambda:PassCapacityProvider",
      "Resource": "arn:aws:lambda:*:*:capacity-provider:trusted-workloads-*"
    }
  ]
}
```

Service-Linked Role

AWS Lambda uses the `AWSServiceRoleForLambda` service-linked role to manage Lambda Managed Instances ec2 resources in your capacity providers.

Best Practices

1. **Separate by Trust Level:** Create different capacity providers for workloads with different security requirements
2. **Use Descriptive Names:** Name capacity providers to clearly indicate their intended use and trust level (e.g., `production-trusted`, `dev-sandbox`)
3. **Apply Least Privilege:** Grant `PassCapacityProvider` permissions only for necessary capacity providers
4. **Monitor Usage:** Use AWS CloudTrail to monitor capacity provider assignments and access patterns

Next steps

- Understand [scaling for Lambda Managed Instances](#)
- Configure [VPC connectivity for your capacity providers](#)
- Review runtime-specific guides for [Java](#), [Node.js](#), and [Python](#)

Lambda operator role for Lambda Managed Instances

When you use Lambda Managed Instances, Lambda needs permissions to manage compute capacity in your account. The operator role provides these permissions through IAM policies that allow Lambda to manage EC2 instances in the capacity provider.

Lambda assumes the operator role when performing these management operations, similar to how Lambda assumes an execution role when your function runs.

Creating an operator role

You can create an operator role in the IAM console or with the AWS CLI. The role must include:

- **Permissions policy** – Grants permissions to manage capacity providers and associated resources
- **Trust policy** – Allows the Lambda service (`lambda.amazonaws.com`) to assume the role

Permissions policy

The operator role needs permissions to manage capacity providers and the underlying compute resources. At minimum, the role requires the permissions in the [AWSLambdaManagedEC2ResourceOperator](#) managed policy, currently:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "ec2:RunInstances",
        "ec2:CreateTags",
        "ec2:AttachNetworkInterface"
      ],
    }
  ],
}
```

```

    "Resource": [
      "arn:aws:ec2:*:*:instance/*",
      "arn:aws:ec2:*:*:network-interface/*",
      "arn:aws:ec2:*:*:volume/*"
    ],
    "Condition": {
      "StringEquals": {
        "ec2:ManagedResourceOperator": "scaler.lambda.amazonaws.com"
      }
    }
  },
  {
    "Effect": "Allow",
    "Action": [
      "ec2:DescribeAvailabilityZones",
      "ec2:DescribeCapacityReservations",
      "ec2:DescribeInstances",
      "ec2:DescribeInstanceStatus",
      "ec2:DescribeInstanceTypeOfferings",
      "ec2:DescribeInstanceTypes",
      "ec2:DescribeSecurityGroups",
      "ec2:DescribeSubnets"
    ],
    "Resource": "*"
  },
  {
    "Effect": "Allow",
    "Action": [
      "ec2:RunInstances",
      "ec2:CreateNetworkInterface"
    ],
    "Resource": [
      "arn:aws:ec2:*:*:subnet/*",
      "arn:aws:ec2:*:*:security-group/*"
    ]
  },
  {
    "Effect": "Allow",
    "Action": [
      "ec2:RunInstances"
    ],
    "Resource": [
      "arn:aws:ec2:*:*:image/*"
    ]
  },

```

```
    "Condition": {
      "StringEquals": {
        "ec2:Owner": "amazon"
      }
    }
  ]
}
```

Trust policy

The trust policy allows Lambda to assume the operator role:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
```

Service-Linked Role for Lambda Managed Instances

To responsibly manage the lifecycle of Lambda Managed Instances, Lambda requires persistent access to terminate managed instances in your account. Lambda uses an AWS Identity and Access Management (IAM) service-linked role (SLR) to perform these operations.

Automatic creation: The service-linked role is automatically created the first time you create a capacity provider. The user creating the first capacity provider must have the `iam:CreateServiceLinkedRole` permission for the `lambda.amazonaws.com` principal.

Permissions: The service-linked role grants Lambda the following permissions on managed instances:

- `ec2:TerminateInstances` – To terminate instances at the end of their lifecycle
- `ec2:DescribeInstances` – To enumerate managed instances

Deletion: You can only delete this service-linked role after you have deleted all Lambda Managed Instances capacity providers in your account.

For more information about service-linked roles, see [the section called “Using service-linked roles”](#).

Understanding the Lambda Managed Instances execution environment

Lambda Managed Instances provide an alternative deployment model that runs your function code on customer-owned Amazon EC2 instances while Lambda manages the operational aspects. The execution environment for Managed Instances has several important differences from Lambda (default) functions, particularly in how it handles concurrent invocations and manages container lifecycles.

Note: For information about the Lambda (default) execution environment, see [Understanding the Lambda execution environment lifecycle](#).

Execution environment lifecycle

The lifecycle of a Lambda Managed Instances function execution environment differs from Lambda (default) in several key ways:

Init phase

During the Init phase, Lambda performs the following steps:

- Initialize and register all extensions
- Bootstrap the runtime entrypoint. Runtime spawns the configured number of runtime workers (implementation depends on runtime)
- Run function initialization code (code outside the handler)
- Wait for at least one runtime worker to signal readiness by calling `/runtime/invocation/next`

The Init phase is considered complete when extensions have initialized and at least one runtime worker has called `/runtime/invocation/next`. The function is then ready to process invocations.

Note

For Lambda Managed Instances functions, initialization can take up to 15 minutes. The timeout is the maximum of 130 seconds or the configured function timeout (up to 900 seconds).

Invoke phase

The Invoke phase for Lambda Managed Instances functions has several unique characteristics:

Continuous operation. Unlike Lambda (default), the execution environment remains continuously active, processing invocations as they arrive without freezing between invocations.

Parallel processing. Multiple invocations can execute simultaneously within the same execution environment, each handled by a different runtime worker.

Independent timeouts. The function's configured timeout applies to each individual invocation. When an invocation times out, Lambda marks that specific invocation as failed but does not interrupt other running invocations or terminate the execution environment.

Backpressure handling. If all runtime workers are busy processing invocations, new invocation requests are rejected until a worker becomes available.

Error handling and recovery

Error handling in Lambda Managed Instances function execution environments differs from Lambda (default):

Invoke timeouts. When an individual invocation times out, Lambda returns a timeout error for that invocation. However, Lambda Managed Instances does not enforce the timeout—your code will keep running. As a function developer, you are responsible for detecting and handling the timeout. The context object exposes the remaining time for the invocation, with a zero or negative value indicating a timeout. Other concurrent invocations in the execution environment continue processing normally.

Runtime worker failures. If a runtime worker process crashes, the execution environment continues operating with the remaining healthy workers.

Extension crashes. If an extension process crashes during initialization or operation, the entire execution environment is marked as unhealthy and is terminated. Lambda creates a new execution environment to replace it.

No reset/repair. Unlike Lambda (default), Managed Instances do not attempt to reset and reinitialize the execution environment after errors. Instead, unhealthy containers are terminated and replaced with new ones.

\$LATEST.PUBLISHED version in Lambda Managed Instances

Lambda Managed Instances functions support the same numbered versioning workflow as Lambda (default). If you prefer not to maintain numbered versions, Lambda Managed Instances introduces a new version type: `$LATEST.PUBLISHED`. This version allows you to create or republish a latest published version as needed with updated code or configuration, without managing numbered versions.

Key difference from `$LATEST`: When you invoke a Lambda Managed Instances function using an unqualified ARN, Lambda implicitly invokes the `$LATEST.PUBLISHED` version rather than the unpublished `$LATEST` version.

The following AWS CLI command creates or republishes the `$LATEST.PUBLISHED` version.

```
aws lambda publish-version --function-name my-function --publish-to LATEST_PUBLISHED
```

You should see the following output:

```
{
  "FunctionName": "my-function",
  "FunctionArn": "arn:aws:lambda:us-east-2:123456789012:function:my-function:
$LATEST.PUBLISHED",
  "Version": "$LATEST.PUBLISHED",
  "Role": "arn:aws:iam::123456789012:role/lambda-role",
  "Handler": "function.handler",
  "Runtime": "nodejs24.x",
  ...
}
```

Note

If you use AWS CloudFormation or the Lambda console to create a Lambda Managed Instances function, Lambda automatically creates the `$LATEST.PUBLISHED` version.

Lambda Managed Instances runtimes

Lambda processes requests differently when using Lambda Managed Instances. Instead of handling requests sequentially in each execution environment, Lambda Managed Instances process multiple requests concurrently within each execution environment. This change in execution model means that functions using Lambda Managed Instances need to consider thread safety, state management, and context isolation, concerns which do not arise in the Lambda (default) single-concurrency model. In addition, the multi-concurrency implementation varies between runtimes.

Supported runtimes

The following runtimes support Lambda Managed Instances:

- **Java:** Java 21 and later.
- **Python:** Python 3.13 and later.
- **Node.js:** Node.js 22 and later.
- **.NET:** .NET 8 and later.

Runtime-specific considerations

Each runtime implements multi-concurrency differently. You need to understand how multi-concurrency is implemented in your chosen programming language to apply the appropriate concurrency best practices.

Java

Uses a single process with OS threads for concurrency. Multiple threads execute the handler method simultaneously, requiring thread-safe handling of state and shared resources.

Python

Uses multiple Python processes where each concurrent request runs in a separate process. This protects against most concurrency issues, though care is required for shared resources such as the `/tmp` directory.

Node.js

Uses [worker threads](#) with asynchronous execution. Concurrent requests are distributed across worker threads, and each worker thread can also handle concurrent requests asynchronously, requiring safe handling of state and shared resources.

.NET

Uses .NET Tasks with asynchronous processing of multiple concurrent requests. Requires safe handling of state and shared resources.

Next steps

For detailed information about each runtime, see the following topics:

- [Java runtime for Lambda Managed Instances](#)
- [Node.js runtime for Lambda Managed Instances](#)
- [Python runtime for Lambda Managed Instances](#)
- [.NET runtime for Lambda Managed Instances](#)

Java runtime for Lambda Managed Instances

For Java runtimes, Lambda Managed Instances use OS threads for concurrency. Lambda loads your handler object once per execution environment during initialization and then creates multiple threads. These threads execute in parallel and require thread-safe handling of state and shared resources. Each thread shares the same handler object and any static fields.

Concurrency configuration

The maximum number of concurrent requests which Lambda sends to each execution environment is controlled by the `PerExecutionEnvironmentMaxConcurrency` setting in the function configuration. This is an optional setting, and the default value varies depending on the runtime. For Java runtimes, the default is 32 concurrent requests per vCPU, or you can configure your own value. This value also determines the number of threads used by the Java runtime. Lambda

automatically adjusts the number of concurrent requests up to the configured maximum based on the capacity of each execution environment to absorb those requests.

Building functions for multi-concurrency

You should apply the same thread safety practices when using Lambda Managed Instances as you would in any other multi-threaded environment. Since the handler object is shared across all runtime worker threads, any mutable state must be thread-safe. This includes collections, database connections, and any static objects that are modified during request processing.

AWS SDK clients are thread safe and do not require special handling.

Example: Database connection pools

The following code uses a static database connection object which is shared between threads. Depending on the connection library used, this may not be thread safe.

```
public class DBQueryHandler implements RequestHandler<Object, String> {
    // Single connection shared across all threads - NOT SAFE
    private static Connection connection;

    public DBQueryHandler() {
        this.connection = DriverManager.getConnection(jdbcUrl, username, password);
    }

    @Override
    public String handleRequest(Object input, Context context) {
        PreparedStatement stmt = connection.prepareStatement(query);
        ResultSet rs = stmt.executeQuery();
        // Multiple threads using same connection causes issues
        return result.toString();
    }
}
```

A thread-safe approach is to use a connection pool. In the following example, the function handler retrieves a connection from the pool. The connection is only used in the context of a single request.

```
public class DBQueryHandler implements RequestHandler<Object, String> {

    private static HikariDataSource dataSource;

    public DBQueryHandler() {
        HikariConfig config = new HikariConfig();
```

```

        config.setJdbcUrl("jdbc:mysql://localhost:3306/your_database");
        dataSource = new HikariDataSource(config); // Create pool once per Lambda
        container
        }

        @Override
        public String handleRequest(Object input, Context context) {
            String query = "SELECT column_name FROM your_table LIMIT 10";
            StringBuilder result = new StringBuilder("Data:\n");

            // try-with-resources automatically calls close() on the connection,
            // which returns it to the HikariCP pool (does NOT close the physical DB
            connection)
            try (Connection connection = dataSource.getConnection();
                PreparedStatement stmt = connection.prepareStatement(query);
                ResultSet rs = stmt.executeQuery()) {

                while (rs.next()) {
                    result.append(rs.getString("column_name")).append("\n");
                }

            } catch (Exception e) {
                context.getLogger().log("Error: " + e.getMessage());
                return "Error";
            }

            return result.toString();
        }
    }
}

```

Example: Collections

Standard Java collections are not thread safe:

```

public class Handler implements RequestHandler<Object, String> {
    private static List<String> items = new ArrayList<>();
    private static Map<String, Object> cache = new HashMap<>();

    @Override
    public String handleRequest(Object input, Context context) {
        items.add("list item"); // Not thread-safe
        cache.put("key", input); // Not thread-safe
        return "Success";
    }
}

```

```
}
```

Instead, use thread-safe collections:

```
public class Handler implements RequestHandler<Object, String> {
    private static final List<String> items =
        Collections.synchronizedList(new ArrayList<>());
    private static final ConcurrentHashMap<String, Object> cache =
        new ConcurrentHashMap<>();

    @Override
    public String handleRequest(Object input, Context context) {
        items.add("list item"); // Thread-safe
        cache.put("key", input); // Thread-safe
        return "Success";
    }
}
```

Shared /tmp directory

The /tmp directory is shared across all concurrent requests in the execution environment. Concurrent writes to the same file can cause data corruption, for example if another process overwrites the file. To address this, either implement file locking for shared files or use unique file names per thread or per request to avoid conflicts. Remember to clean up unneeded files to avoid exhausting the available space.

Logging

Log interleaving (log entries from different requests being interleaved in logs) is normal in multi-concurrent systems.

Functions using Lambda Managed Instances always use the structured JSON log format introduced with [advanced logging controls](#). This format includes the requestId, allowing log entries to be correlated to a single request. When you use the `LambdaLogger` object from `context.getLogger()` the requestId is automatically included in each log entry. For further information, see [the section called “Using Lambda advanced logging controls with Java”](#).

Request context

The context object is bound to the request thread. Using `context.getAwsRequestId()` provides thread-safe access to the request ID for the current request.

Use `context.getXrayTraceId()` to access the X-Ray trace ID. This provides thread-safe access to the trace ID for the current request. Lambda does not support the `_X_AMZN_TRACE_ID` environment variable with Lambda Managed Instances. The X-Ray trace ID is propagated automatically when using the AWS SDK.

Use `com.amazonaws.services.lambda.runtime.Context.getRemainingTimeInMillis()` to detect timeouts. See [the section called “Error handling and recovery”](#) for more information.

If you use virtual threads in your program or create threads during initialization, you will need to pass any required request context to these threads.

Initialization and shutdown

Function initialization occurs once per execution environment. Objects created during initialization are shared across threads.

For Lambda functions with extensions, the execution environment emits a `SIGTERM` signal during shut down. This signal is used by extensions to trigger clean up tasks, such as flushing buffers. You can subscribe to `SIGTERM` events to trigger function clean-up tasks, such as closing database connections. To learn more about the execution environment lifecycle, see [the section called “Execution environment”](#).

Dependency versions

Lambda Managed Instances requires the following minimum package versions:

- AWS SDK for Java 2.0: version 2.34.0 or later
- AWS X-Ray SDK for Java: version 2.20.0 or later
- AWS Distro for OpenTelemetry - Instrumentation for Java: version 2.20.0 or later
- Powertools for AWS Lambda (Java): version 2.8.0 or later

Powertools for AWS Lambda (Java)

Powertools for AWS Lambda (Java) is compatible with Lambda Managed Instances and provides utilities for logging, tracing, metrics, and more. For more information, see [Powertools for AWS Lambda \(Java\)](#).

Next steps

- Review [Node.js runtime for Lambda Managed Instances](#)
- Review [Python runtime for Lambda Managed Instances](#)
- Review [.NET runtime for Lambda Managed Instances](#)
- Learn about [scaling Lambda Managed Instances](#)

Node.js runtime for Lambda Managed Instances

For Node.js runtimes, Lambda Managed Instances uses worker threads with `async/await`-based execution to handle concurrent requests. Function initialization occurs once per worker thread. Concurrent invocations are handled across two dimensions: worker threads provide parallelism across vCPUs, and asynchronous execution provides concurrency within each thread. Each concurrent request handled by the same worker thread shares the same handler object and global state, requiring safe handling under multiple concurrent requests.

Maximum concurrency

The maximum number of concurrent requests which Lambda sends to each execution environment is controlled by the `PerExecutionEnvironmentMaxConcurrency` setting in the function configuration. This is an optional setting, and the default value varies depending on the runtime. For Node.js runtimes, the default is 64 concurrent requests per vCPU, or you can configure your own value. Lambda automatically adjusts the number of concurrent requests up to the configured maximum based on the capacity of each execution environment to absorb those requests.

For Node.js, the number of concurrent requests that each execution environment can process is determined by the number of worker threads and the capacity of each worker thread to process concurrent requests asynchronously. The default number of worker threads is determined by the number of vCPUs available, or you can configure the number of worker threads by setting the `AWS_LAMBDA_NODEJS_WORKER_COUNT` environment variable. We recommend using `async` function handlers since this allows processing multiple requests per worker thread. If your function handler is synchronous, each worker thread can only process a single request at a time.

Building functions for multi-concurrency

With an `async` function handler, each runtime worker processes multiple requests concurrently. Global objects will be shared across multiple concurrent requests. For mutable objects, avoid using global state or use `AsyncLocalStorage`.

AWS SDK clients are async safe and do not require special handling.

Example: Global state

The following code uses a global object which is mutated inside the function handler. This is not async-safe.

```
let state = {
  currentUser: null,
  requestData: null
};

export const handler = async (event, context) => {
  state.currentUser = event.userId;
  state.requestData = event.data;

  await processData(state.requestData);

  // state.currentUser might now belong to a different request
  return { user: state.currentUser };
};
```

Initialising the state object inside the function handler avoids shared global state.

```
export const handler = async (event, context) => {
  let state = {
    currentUser: event.userId,
    requestData: event.data
  };

  await processData(state.requestData);

  return { user: state.currentUser };
};
```

Example: Database connections

The following code uses a shared client object which is shared between multiple invocations. Depending on the connection library used, this may not be concurrency safe.

```
const { Client } = require('pg');
```

```
// Single connection created at init time
const client = new Client({
  host: process.env.DB_HOST,
  database: process.env.DB_NAME,
  user: process.env.DB_USER,
  password: process.env.DB_PASSWORD
});

// Connect once during cold start
client.connect();

exports.handler = async (event) => {
  // Multiple parallel invocations share this single connection = BAD
  // With multi-concurrent Lambda, queries will collide
  const result = await client.query('SELECT * FROM users WHERE id = $1',
    [event.userId]);

  return {
    statusCode: 200,
    body: JSON.stringify(result.rows[0])
  };
};
```

A concurrency-safe approach is to use a connection pool. The pool uses a separate connection for each concurrent database query.

```
const { Pool } = require('pg');

// Connection pool created at init time
const pool = new Pool({
  host: process.env.DB_HOST,
  database: process.env.DB_NAME,
  user: process.env.DB_USER,
  password: process.env.DB_PASSWORD,
  max: 20, // Max connections in pool
  idleTimeoutMillis: 30000,
  connectionTimeoutMillis: 2000
});

exports.handler = async (event) => {
  // Pool gives each parallel invocation its own connection
  const result = await pool.query('SELECT * FROM users WHERE id = $1', [event.userId]);
```

```
return {  
    statusCode: 200,  
    body: JSON.stringify(result.rows[0])  
};  
};
```

Node.js 22 callback-based handlers

When using Node.js 22, you cannot use a callback-based function handler with Lambda Managed Instances. Callback-based handlers are only supported for Lambda (default) functions. For Node.js 24 and later runtimes, callback-based function handlers are deprecated for both Lambda (default) and Lambda Managed Instances.

Instead, use an async function handler when using Lambda Managed Instances. For more information, see [Define Lambda function handler in Node.js](#).

Shared /tmp directory

The /tmp directory is shared across all concurrent requests in the execution environment. Concurrent writes to the same file can cause data corruption, for example if another process overwrites the file. To address this, either implement file locking for shared files or use unique file names per request to avoid conflicts. Remember to clean up unneeded files to avoid exhausting the available space.

Logging

Log interleaving (log entries from different requests being interleaved in logs) is normal in multi-concurrent systems. Functions using Lambda Managed Instances always use the structured JSON log format introduced with [advanced logging controls](#). This format includes the `requestId`, allowing log entries to be correlated to a single request. When you use the `console` logger, the `requestId` is automatically included in each log entry. For further information, see [the section called “Using Lambda advanced logging controls with Node.js”](#).

Popular third-party logging libraries, such as [Winston](#), typically include support for using `console` for log output.

Request context

Using `context.awsRequestId` provides async-safe access to the request ID for the current request.

Use `context.xRayTraceId` to access the X-Ray trace ID. This provides concurrency-safe access to the trace ID for the current request. Lambda does not support the `_X_AMZN_TRACE_ID` environment variable with Lambda Managed Instances. The X-Ray trace ID is propagated automatically when using the AWS SDK.

Use `context.getRemainingTimeInMillis()` to detect timeouts. See [the section called “Error handling and recovery”](#) for more information.

Initialization and shutdown

Function initialization occurs once per worker thread. You may see repeat log entries if your function emits logs during initialization.

For Lambda functions with extensions, the execution environment emits a `SIGTERM` signal during shut down. This signal is used by extensions to trigger clean up tasks, such as flushing buffers. Lambda (default) functions with extensions can also subscribe to the `SIGTERM` signal using `process.on()`. This is not supported for functions using Lambda Managed Instances since `process.on()` cannot be used with worker threads. To learn more about the execution environment lifecycle, see [the section called “Execution environment”](#).

Dependency versions

Lambda Managed Instances requires the following minimum package versions:

- AWS SDK for JavaScript v3: version 3.933.0 or later
- AWS X-Ray SDK for Node.js: version 3.12.0 or later
- AWS Distro for OpenTelemetry - Instrumentation for JavaScript: version 0.8.0 or later
- Powertools for AWS Lambda (TypeScript): version 2.29.0 or later

Powertools for AWS Lambda (TypeScript)

Powertools for AWS Lambda (TypeScript) is compatible with Lambda Managed Instances and provides utilities for logging, tracing, metrics, and more. For more information, see [Powertools for AWS Lambda \(TypeScript\)](#).

Next steps

- Review [Java runtime for Lambda Managed Instances](#)
- Review [Python runtime for Lambda Managed Instances](#)

- Review [.NET runtime for Lambda Managed Instances](#)
- Learn about [scaling Lambda Managed Instances](#)

Python runtime for Lambda Managed Instances

The Lambda runtime uses multiple Python processes to handle concurrent requests. Each concurrent request runs in a separate process with its own memory space and initialization. Each process handles one request at a time, synchronously. Processes don't share memory directly, so global variables, module-level caches, and singleton objects are isolated between concurrent requests.

Concurrency configuration

The maximum number of concurrent requests which Lambda sends to each execution environment is controlled by the `PerExecutionEnvironmentMaxConcurrency` setting in the function configuration. This is an optional setting, and the default value varies depending on the runtime. For Python runtimes, the default is 16 concurrent requests per vCPU, or you can configure your own value. This value also determines the number of processes used by the Python runtime. Lambda automatically adjusts the number of concurrent requests up to the configured maximum based on the capacity of each execution environment to absorb those requests.

Important

Using process-based concurrency means each runtime worker process performs its own initialization. Total memory usage equals the per-process memory multiplied by the number of concurrent processes. If you are loading large libraries or data sets and have high concurrency, you will have a large memory footprint. According to your workload, you may need to tune your CPU-to-memory ratio or use a lower concurrency setting to avoid exceeding the available memory. You can use the `MemoryUtilization` metric in CloudWatch to track memory consumption.

Building functions for multi-concurrency

Due to the process-based multi-concurrency model, Lambda Managed Instances functions using Python runtimes do not access in-memory resources concurrently from multiple invokes. You do not need to apply coding practices for in-memory concurrency safety.

Shared /tmp directory

The /tmp directory is shared across all concurrent requests in the execution environment. Concurrent writes to the same file can cause data corruption, for example if another process overwrites the file. To address this, either implement file locking for shared files or use unique file names per process or per request to avoid conflicts. Remember to clean up unneeded files to avoid exhausting the available space.

Logging

Log interleaving (log entries from different requests being interleaved in logs) is normal in multi-concurrent systems.

Functions using Lambda Managed Instances always use the structured JSON log format introduced with [advanced logging controls](#). This format includes the `requestId`, allowing log entries to be correlated to a single request. When you use the logging module from the Python standard library in Lambda, the `requestId` is automatically included in each log entry. For further information, see [Using Lambda advanced logging controls with Python](#).

Request context

Use `context.aws_request_id` to access to the request ID for the current request.

With Python runtimes, you can use the `_X_AMZN_TRACE_ID` environment variable to access the X-Ray trace ID with Lambda Managed Instances. The X-Ray trace ID is propagated automatically when using the AWS SDK.

Use `context.get_remaining_time_in_millis()` to detect timeouts. See [the section called “Error handling and recovery”](#) for more information.

Initialization and shutdown

Function initialization occurs once per process. You may see repeat log entries if your function emits logs during initialization.

For Lambda functions with extensions, the execution environment emits a SIGTERM signal during shut down. This signal is used by extensions to trigger clean up tasks, such as flushing buffers. You can subscribe to SIGTERM events to trigger function clean-up tasks, such as closing database connections. To learn more about the execution environment lifecycle, see [the section called “Execution environment”](#).

Dependency versions

Lambda Managed Instances requires the following minimum package versions:

- Powertools for AWS Lambda (Python): version 3.23.0 or later

Powertools for AWS Lambda (Python)

Powertools for AWS Lambda (Python) is compatible with Lambda Managed Instances and provides utilities for logging, tracing, metrics, and more. For more information, see [Powertools for AWS Lambda \(Python\)](#).

Next steps

- Review [Java runtime for Lambda Managed Instances](#)
- Review [Node.js runtime for Lambda Managed Instances](#)
- Review [.NET runtime for Lambda Managed Instances](#)
- Learn about [scaling Lambda Managed Instances](#)

.NET runtime for Lambda Managed Instances

For .NET runtimes, Lambda Managed Instances use a single .NET process per execution environment. Multiple concurrent requests are processed using .NET Tasks.

Concurrency configuration

The maximum number of concurrent requests which Lambda sends to each execution environment is controlled by the `PerExecutionEnvironmentMaxConcurrency` setting in the function configuration. This is an optional setting, and the default value varies depending on the runtime. For .NET runtimes, the default is 32 concurrent requests per vCPU, or you can configure your own value. Lambda automatically adjusts the number of concurrent requests up to the configured maximum based on the capacity of each execution environment to absorb those requests.

Building functions for multi-concurrency

You should apply the same concurrency safety practices when using Lambda Managed Instances as you would in any other multi-concurrent environment. Since the handler object is shared across all

Tasks any mutable state must be thread-safe. This includes collections, database connections and any static objects that are modified during request processing.

AWS SDK clients are thread safe and do not require special handling.

Example: Database connection pools

The following code uses a static database connection object which is shared between concurrent requests. The `SqlConnection` object is not thread safe.

```
public class DBQueryHandler
{
    // Single connection shared across threads - NOT SAFE
    private SqlConnection connection;

    public DBQueryHandler()
    {
        connection = new SqlConnection("your-connection-string-here");
        connection.Open();
    }

    public string Handle(object input, ILambdaContext context)
    {
        using var cmd = connection.CreateCommand();
        cmd.CommandText = "SELECT ..."; // your query

        using var reader = cmd.ExecuteReader();

        ...
    }
}
```

To address this, use a separate connection for each request, drawn from a connection pool. ADO.NET providers like `Microsoft.Data.SqlClient` automatically support connection pooling when the connection object is opened.

```
public class DBQueryHandler
{
    public DBQueryHandler()
    {
    }
}
```

```
public string Handle(object input, ILambdaContext context)
{
    using var connection = new SqlConnection("your-connection-string-here");
    connection.Open();
    using var cmd = connection.CreateCommand();
    cmd.CommandText = "SELECT ..."; // your query

    using var reader = cmd.ExecuteReader();

    ...
}
}
```

Example: Collections

Standard .NET collections are not thread safe:

```
public class Handler
{
    private static List<string> items = new List<string>();
    private static Dictionary<string, object> cache = new Dictionary<string, object>();

    public string FunctionHandler(object input, ILambdaContext context)
    {
        items.Add(context.AwsRequestId);
        cache["key"] = input;

        return "Success";
    }
}
```

Use collections from the `System.Collections.Concurrent` namespace for concurrency safety:

```
public class Handler
{
    private static ConcurrentBag<string> items = new ConcurrentBag<string>();
    private static ConcurrentDictionary<string, object> cache = new
    ConcurrentDictionary<string, object>();

    public string FunctionHandler(object input, ILambdaContext context)
    {
        items.Add(context.AwsRequestId);
        cache["key"] = input;
    }
}
```

```
        return "Success";  
    }  
}
```

Shared /tmp directory

The /tmp directory is shared across all concurrent requests in the execution environment. Concurrent writes to the same file can cause data corruption, for example if another request overwrites the file. To address this, either implement file locking for shared files or use unique file names per request to avoid conflicts. Remember to clean up unneeded files to avoid exhausting the available space.

Logging

Log interleaving (log entries from different requests being interleaved in logs) is normal in multi-concurrent systems. Functions using Lambda Managed Instances always use the structured JSON log format introduced with [advanced logging controls](#). This format includes the `requestId`, allowing log entries to be correlated to a single request. When you use the `context.Logger` object to generate logs, the `requestId` is automatically included in each log entry. For further information, see [the section called "Using Lambda advanced logging controls with .NET"](#).

Request context

Use the `context.AwsRequestId` property to access to the request ID for the current request.

Use the `context.TraceId` property to access the X-Ray trace ID. This provides concurrency-safe access to the trace ID for the current request. Lambda does not support the `_X_AMZN_TRACE_ID` environment variable with Lambda Managed Instances. The X-Ray trace ID is propagated automatically when using the AWS SDK.

Use `ILambdaContext.RemainingTime` to detect timeouts. See [the section called "Error handling and recovery"](#) for more information.

Initialization and shutdown

Function initialization occurs once per execution environment. Objects created during initialization are shared across requests.

For Lambda functions with extensions, the execution environment emits a `SIGTERM` signal during shut down. This signal is used by extensions to trigger clean up tasks, such as flushing buffers.

You can subscribe to SIGTERM events to trigger function clean-up tasks, such as closing database connections. To learn more about the execution environment lifecycle, see [the section called “Execution environment”](#).

Dependency versions

Lambda Managed Instances requires the following minimum package versions:

- Amazon.Lambda.Core: version 2.7.1 or later
- Amazon.Lambda.RuntimeSupport: version 1.14.1 or later
- OpenTelemetry.Instrumentation.AWSLambda: version 1.14.0 or later
- AWSXRayRecorder.Core: version 2.16.0 or later
- AWSSDK.Core: version 4.0.0.32 or later

Powertools for AWS Lambda (.NET)

[Powertools for AWS Lambda \(.NET\)](#) and [AWS Distro for OpenTelemetry - Instrumentation for DotNet](#) currently do not support Lambda Managed Instances.

Networking for Lambda Managed Instances

When running Lambda Managed Instances functions, you need to configure network connectivity to enable your functions to access resources outside the VPC. This includes AWS services such as Amazon S3 and DynamoDB. The connectivity is also needed for transmitting telemetry data to CloudWatch Logs and X-Ray.

Connectivity options

There are three primary approaches for configuring VPC connectivity, each with different trade-offs for cost, security, and complexity.

Public subnet with an internet gateway

This option uses a public subnet with direct internet access through an internet gateway. You can choose between IPv4 and IPv6 configurations.

IPv4 with internet gateway

To configure IPv4 connectivity with an internet gateway

1. Create or use an existing public subnet with an IPv4 CIDR block.
2. Attach an internet gateway to your VPC.
3. Update the route table to route `0.0.0.0/0` traffic to the internet gateway.
4. Ensure resources have public IPv4 addresses or Elastic IP addresses assigned.
5. Configure security groups to allow outbound traffic on the required ports.

This configuration provides bidirectional connectivity, allowing both outbound connections from your functions and inbound connections from the internet.

IPv6 with internet gateway

To configure IPv6 connectivity with an internet gateway

1. Enable IPv6 on your VPC.
2. Create or use an existing public subnet with an IPv6 CIDR block assigned.
3. Attach an internet gateway to your VPC (the same internet gateway can handle both IPv4 and IPv6).
4. Update the route table to route `::/0` traffic to the internet gateway.
5. Verify that the AWS services you need to access support IPv6 in your Region.
6. Configure security groups to allow outbound traffic on the required ports.

This configuration provides bidirectional connectivity using IPv6 addressing.

IPv6 with egress-only internet gateway

To configure IPv6 connectivity with an egress-only internet gateway

1. Enable IPv6 on your VPC.
2. Create or use an existing public subnet with an IPv6 CIDR block assigned.
3. Attach an egress-only internet gateway to your VPC.
4. Update the route table to route `::/0` traffic to the egress-only internet gateway.
5. Verify that the AWS services you need to access support IPv6 in your Region.
6. Configure security groups to allow outbound traffic on the required ports.

This configuration provides outbound-only connectivity, preventing inbound connections from the internet while allowing your functions to initiate outbound connections.

VPC endpoints

VPC endpoints enable you to privately connect your VPC to supported AWS services without requiring an internet gateway, NAT device, VPN connection, or AWS Direct Connect connection. Traffic between your VPC and the AWS service does not leave the Amazon network.

To configure VPC endpoints

1. Open the Amazon VPC console at console.aws.amazon.com/vpc/.
2. In the navigation pane, choose **Endpoints**.
3. Choose **Create endpoint**.
4. For **Service category**, choose **AWS services**.
5. For **Service name**, select the service endpoint you need (for example, `com.amazonaws.region.s3` for Amazon S3).
6. For **VPC**, select your VPC.
7. For **Subnets**, select the subnets where you want to create endpoint network interfaces. For high availability, select subnets in multiple Availability Zones.
8. For **Security groups**, select the security groups to associate with the endpoint network interfaces. The security groups must allow inbound traffic from your function's security group on the required ports.
9. Choose **Create endpoint**.

Repeat these steps for each AWS service that your functions need to access.

Private subnet with NAT gateway

This option uses a NAT gateway to provide internet access for resources in private subnets while keeping the resources private.

To configure a private subnet with NAT gateway

1. Create a public subnet (if one doesn't already exist) with a CIDR block.
2. Attach an internet gateway to your VPC.
3. Create a NAT gateway in the public subnet and assign an Elastic IP address.
4. Update the public subnet route table to add a route: `0.0.0.0/0` → internet gateway.
5. Create or use an existing private subnet with a CIDR block.
6. Update the private subnet route table to add a route: `0.0.0.0/0` → NAT gateway.
7. Configure security groups to allow outbound traffic on the required ports.

For high availability, deploy one NAT gateway in each Availability Zone and configure route tables per Availability Zone to use the local NAT gateway. This prevents cross-AZ data transfer charges and improves resilience.

Choosing a connectivity option

Consider the following factors when choosing a connectivity option:

Public subnet with internet gateway

- Simplest configuration with lowest cost
- Suitable for development and testing environments
- Resources can receive inbound connections from the internet (security consideration)
- Supports both IPv4 and IPv6

VPC endpoints

- Highest security, traffic stays within the AWS network
- Lower latency compared to internet routing
- Recommended for production environments with strict security requirements
- Higher cost per endpoint, per Availability Zone, and per GB processed

- Requires an endpoint in each Availability Zone for high availability

Private subnet with NAT gateway

- Resources remain private with no inbound internet access
- Standard enterprise architecture pattern
- Supports all IPv4 internet traffic
- Moderate cost with NAT gateway hourly and data processing charges
- Supports IPv4 only

Monitoring Lambda Managed Instances

You can monitor Lambda Managed Instances using CloudWatch metrics. Lambda automatically publishes metrics to CloudWatch to help you monitor resource utilization, track costs, and optimize performance.

Available metrics

Lambda Managed Instances provides metrics at two levels: capacity provider level and execution environment level.

Capacity provider level metrics

Capacity provider level metrics provide visibility into overall resource utilization across your instances. These metrics use the following dimensions:

- **CapacityProviderName** - The name of your capacity provider
- **InstanceType** - The EC2 instance type

Resource utilization metrics:

- **CPUUtilization** - The percentage of CPU utilization across instances in the capacity provider
- **MemoryUtilization** - The percentage of memory utilization across instances in the capacity provider
- **NetworkOut** - Network traffic sent through the customer ENI (in bytes)
- **NetworkIn** - Network traffic received through the customer ENI (in bytes)
- **DiskReadBytes** - Read traffic from local storage across instances (in bytes)
- **DiskWriteBytes** - Write traffic to local storage across instances (in bytes)

Capacity metrics:

- **vCPUsAvailable** - The amount of vCPU available on instances for allocation (in count)
- **MemoryAvailable** - The amount of memory available on instances for allocation (in bytes)
- **vCPUsAllocated** - The amount of vCPU allocated on instances for execution environments (in count)
- **MemoryAllocated** - The amount of memory allocated on instances for execution environments (in bytes)

Execution environment level metrics

Execution environment level metrics provide visibility into resource utilization and concurrency for individual functions. These metrics use the following dimensions:

- **CapacityProviderName** - The name of your capacity provider
- **FunctionName** - The name of your Lambda function

Available execution environment metrics:

- **ExecutionEnvironmentConcurrency** - The maximum concurrency over a 5-minute sample period
- **ExecutionEnvironmentConcurrencyLimit** - The maximum concurrency limit per execution environment
- **ExecutionEnvironmentCPUUtilization** - The percentage of CPU utilization for the function's execution environments

- **ExecutionEnvironmentMemoryUtilization** - The percentage of memory utilization for the function's execution environments

Metric frequency and retention

Lambda Managed Instances metrics are published at 5-minute intervals and retained for 15 months.

Viewing metrics in CloudWatch

To view Lambda Managed Instances metrics in the CloudWatch console

1. Open the CloudWatch console at console.aws.amazon.com/cloudwatch/.
2. In the navigation pane, choose **Metrics**.
3. In the **All metrics** tab, choose **AWS/Lambda**.
4. Choose the metric dimension you want to view:
 - For capacity provider level metrics, filter by **CapacityProviderName** and **InstanceType**
 - For execution environment level metrics, filter by **CapacityProviderName** and **FunctionName**
5. Select the metrics you want to monitor.

Using metrics to optimize performance

Monitor CPU and memory utilization to understand if your functions are properly sized. High utilization may indicate the need for larger instance types or increased function memory allocation. Track concurrency metrics to understand scaling behavior and identify potential throttling.

Monitor capacity metrics to ensure sufficient resources are available for your workloads. The **vCPUsAvailable** and **MemoryAvailable** metrics help you understand remaining capacity on your instances.

Lambda Managed Instances quotas

This page describes the service quotas for AWS Lambda Managed Instances. These quotas are separate from AWS Lambda (default) quotas. Some quotas can be increased upon request.

Lambda API request quotas

These quotas control the rate at which you can make API calls to manage Lambda Managed Instances capacity providers. The read and write API rate limits apply to all capacity provider operations combined, including creating, updating, describing, and deleting capacity providers.

Resource	Quota
The maximum combined rate (requests per second) for all capacity provider read APIs	15 requests per second. Cannot be increased.
The maximum combined rate (requests per second) for all capacity provider write APIs	1 request per second. Cannot be increased.

Lambda Managed Instances resource quotas

These quotas define the limits for core Lambda Managed Instances resources within your AWS account. They govern the number of capacity providers you can create and the number of function versions that can be associated with each capacity provider.

Resource	Quota
Capacity providers	1,000. The maximum number of capacity providers created in an account.
Function versions per capacity provider	100. The maximum number of function versions per capacity provider. Cannot be increased.

Event source mapping quotas

These quotas control the throughput and configuration limits for processing events from various AWS services on Lambda Managed Instances. The throughput limits ensure predictable performance while the mapping count limits help maintain service stability. Event source mappings on Lambda Managed Instances support Amazon SQS, DynamoDB Streams, Amazon Kinesis Data Streams, Amazon MSK, and self-managed Apache Kafka as event sources.

Resource	Quota
Standard SQS event source mapping throughput on Lambda Managed Instances	5 MB per second. Cannot be increased.
Standard Kafka event source mapping throughput on Lambda Managed Instances	1 MB per second. Cannot be increased.
Standard Kafka event source mappings on Lambda Managed Instances	100 event source mappings. Cannot be increased.
Kinesis event source mapping throughput on Lambda Managed Instances	25 MB per second. Can be increased.
DynamoDB event source mapping throughput on Lambda Managed Instances	10 MB per second. Can be increased.
Invoke request throughput for asynchronous invocations on Lambda Managed Instances	5 MB per second. Can be increased.

Requesting a quota increase

For quotas that can be increased, you can request an increase through the Service Quotas console.

To request a quota increase

1. Open the Service Quotas console at console.aws.amazon.com/servicequotas/.
2. In the navigation pane, choose **AWS services**.
3. Choose **AWS Lambda**.
4. Select the quota you want to increase.

5. Choose **Request quota increase**.
6. Enter the new quota value and provide a justification for the increase.
7. Choose **Request**.

Best practices for Lambda Managed Instances

Capacity provider configuration

Separate capacity providers by trust level. Create different capacity providers for workloads with different security requirements. All functions assigned to the same capacity provider must be mutually trusted, as capacity providers serve as the security boundary.

Use descriptive names. Name capacity providers to clearly indicate their intended use and trust level (for example, `production-trusted`, `dev-sandbox`). This helps teams understand the purpose and security posture of each capacity provider.

Use multiple Availability Zones. Specify subnets across multiple Availability Zones when creating capacity providers. Lambda launches three instances by default for AZ resiliency, ensuring high availability for your functions.

Instance type selection

Let Lambda choose instance types. By default, Lambda chooses the best instance types for your workload. We recommend letting Lambda Managed Instances choose instance types for you, as restricting the number of possible instance types may result in lower availability.

Specify instance types for specific requirements. If you have specific hardware requirements, set allowed instance types to a list of compatible instances. For example:

- For applications requiring high network bandwidth, select several n instance types
- For testing or development environments with cost constraints, choose smaller instance types like m7a.large

Function configuration

Choose appropriate memory and vCPU settings. Select memory and vCPU configurations that support multi-concurrent executions of your function. The minimum supported function size is 2GB and 1 vCPU.

- For Python applications, choose a higher ratio of memory to vCPUs (such as 4 to 1 or 8 to 1) because of the way Python handles multi-concurrency
- For CPU-intensive operations or functions that perform little IO, choose more than one vCPU
- For IO-heavy applications like web services or batch jobs, multi-concurrency provides the most benefit

Configure maximum concurrency appropriately. Lambda chooses sensible defaults for maximum concurrency that balance resource consumption and throughput. Adjust this setting based on your function's resource usage:

- Increase maximum concurrency (up to 64 per vCPU) if your function invocations use very little CPU
- Decrease maximum concurrency if your application consumes a large amount of memory and very little CPU

Note that execution environments with very low concurrency may experience throttles and difficulty scaling.

Scaling configuration

Set appropriate target resource utilization. By default, Lambda maintains enough headroom for your traffic to double within 5 minutes without throttles. Adjust this based on your workload characteristics:

- For very steady workloads or applications not sensitive to throttles, set the target to a high level to achieve higher utilization and lower costs

- For workloads with potential traffic bursts, set resource targets to a low level to maintain additional headroom

Plan for traffic growth. If your traffic more than doubles within 5 minutes, you may see throttles as Lambda scales up instances and execution environments. Design your application to handle potential throttling during rapid scale-up periods.

Security

Apply least privilege for PassCapacityProvider permissions. Grant `lambda:PassCapacityProvider` permissions only for necessary capacity providers. Use resource-level permissions to restrict which capacity providers users can assign to functions.

Monitor capacity provider usage. Use AWS CloudTrail to monitor capacity provider assignments and access patterns. This helps identify unauthorized access attempts and ensures compliance with security policies.

Separate untrusted workloads. Do not rely on containers for security isolation between untrusted workloads. Use different capacity providers to separate workloads that are not mutually trusted.

Cost optimization

Leverage EC2 pricing options. Take advantage of EC2 Savings Plans and Reserved Instances to reduce costs. These pricing options apply to the underlying EC2 compute (the 15% management fee is not discounted).

Optimize for steady-state workloads. Lambda Managed Instances are best suited for steady-state functions with predictable high-volume traffic. For bursty traffic patterns, Lambda (default) may be more cost-effective.

Monitor resource utilization. Track CloudWatch metrics to understand CPU and memory utilization. Adjust function memory allocation and instance type selection based on actual usage patterns to optimize costs.

Monitoring and observability

Monitor capacity provider metrics. Track capacity provider level metrics including `CPUUtilization`, `MemoryUtilization`, `vCPUsAvailable`, and `MemoryAvailable` to ensure sufficient resources are available for your workloads.

Monitor execution environment metrics. Track execution environment level metrics including `ExecutionEnvironmentConcurrency` and `ExecutionEnvironmentConcurrencyLimit` to understand scaling behavior and identify potential throttling.

Set up CloudWatch alarms. Create CloudWatch alarms for key metrics to proactively identify issues:

- High CPU or memory utilization
- Low available capacity
- Approaching concurrency limits

Runtime-specific considerations

Follow runtime-specific best practices. Each runtime handles multi-concurrency differently. Review the runtime-specific guides for detailed recommendations:

- Java: Use thread-safe collections, `AtomicInteger`, and `ThreadLocal` for request-specific state
- Node.js: Use `InvokeStore` for all request-specific state and avoid global variables
- Python: Use unique file names in `/tmp` with request IDs and consider process-based memory isolation

Test for thread safety and concurrency issues. Before deploying to production, thoroughly test your functions for thread safety issues, race conditions, and proper state isolation under concurrent load.

Troubleshooting Lambda Managed Instances

Throttling and scaling issues

High error rates during scale-up

Problem: You experience throttling errors (HTTP 429) when traffic increases rapidly.

Cause: Lambda Managed Instances scale asynchronously based on CPU resource utilization and multi-concurrency saturation. If your traffic more than doubles within 5 minutes, you may see throttles as Lambda scales up instances and execution environments to meet demand.

Solution:

- **Adjust target resource utilization:** If your workload has predictable traffic patterns, set a lower target resource utilization to maintain additional headroom for traffic bursts.
- **Pre-warm capacity:** For planned traffic increases, gradually ramp up traffic over a longer period to allow scaling to keep pace.
- **Monitor scaling metrics:** Track throttle error metrics to understand the reason for throttles and capacity scaling issues.
- **Review function configuration:** Ensure your function memory and vCPU settings support multi-concurrent executions. Increase function memory or vCPU allocation if needed.

Slow scale-down

Problem: Instances take a long time to scale down after traffic decreases.

Cause: Lambda Managed Instances scale down gradually to maintain availability and avoid rapid capacity changes that could impact performance.

Solution:

This is expected behavior. Lambda scales down instances conservatively to ensure stability. Monitor your CloudWatch metrics to track the number of running instances.

Concurrency issues

Execution environments with low concurrency experience throttles

Problem: Your functions experience throttling despite having available capacity.

Cause: Execution environments with very low maximum concurrency may have difficulty scaling effectively. Lambda Managed Instances are designed for multi-concurrent applications.

Solution:

- **Increase maximum concurrency:** If your function invocations use very little CPU, increase the maximum concurrency setting up to 64 per vCPU.
- **Optimize function code:** Review your function code to reduce CPU consumption per invocation, allowing higher concurrency.
- **Adjust function memory and vCPU:** Ensure your function has sufficient resources to handle multiple concurrent invocations.

Thread safety issues (Java runtime)

Problem: Your Java function produces incorrect results or experiences race conditions under load.

Cause: Multiple threads execute the handler method simultaneously, and shared state is not thread-safe.

Solution:

- Use `AtomicInteger` or `AtomicLong` for counters instead of primitive types
- Replace `HashMap` with `ConcurrentHashMap`
- Use `Collections.synchronizedList()` to wrap `ArrayList`
- Use `ThreadLocal` for request-specific state
- Access trace IDs from the Lambda Context object, not environment variables

For detailed guidance, see the [Java runtime for Lambda Managed Instances](#) documentation.

State isolation issues (Node.js runtime)

Problem: Your Node.js function returns data from different requests or experiences data corruption.

Cause: Global variables are shared across concurrent invocations on the same worker thread. When async operations yield control, other invocations can modify shared state.

Solution:

- Install and use `@aws/lambda-invoke-store` for all request-specific state
- Replace global variables with `InvokeStore.set()` and `InvokeStore.get()`
- Use unique file names in `/tmp` with request IDs
- Access trace IDs using `InvokeStore.getXRayTraceId()` instead of environment variables

For detailed guidance, see the [Node.js runtime for Lambda Managed Instances](#) documentation.

File conflicts (Python runtime)

Problem: Your Python function reads incorrect data from files in `/tmp`.

Cause: Multiple processes share the `/tmp` directory. Concurrent writes to the same file can cause data corruption.

Solution:

- Use unique file names with request IDs: `/tmp/request_{context.request_id}.txt`
- Use file locking with `fcntl.flock()` for shared files
- Clean up temporary files with `os.remove()` after use

For detailed guidance, see the [Python runtime for Lambda Managed Instances](#) documentation.

Performance issues

High memory utilization

Problem: Your functions experience high memory utilization or out-of-memory errors.

Cause: Each concurrent request in Python runs in a separate process with its own memory space. Total memory usage equals per-process memory multiplied by concurrent processes.

Solution:

- Monitor the `MemoryUtilization` metric in CloudWatch
- Reduce the `MaxConcurrency` setting if memory usage approaches the function's memory limit
- Increase function memory allocation to support higher concurrency
- Optimize memory usage by loading data on-demand instead of during initialization

Inconsistent performance

Problem: Function performance varies significantly between invocations.

Cause: Lambda may select different instance types based on availability, or functions may be running on instances with varying resource availability.

Solution:

- **Specify allowed instance types:** If you have specific performance requirements, configure allowed instance types in your capacity provider to limit the instance types Lambda can select.
- **Monitor instance-level metrics:** Track `CPUUtilization` and `MemoryUtilization` at the capacity provider level to identify resource constraints.
- **Review capacity metrics:** Check `vCPUsAvailable` and `MemoryAvailable` to ensure sufficient resources are available on your instances.

Capacity provider issues

Function version fails to become ACTIVE

Problem: Your function version remains in a pending state after publishing.

Cause: Lambda is launching Managed Instances and starting execution environments. This process takes time, especially for the first function version on a new capacity provider.

Solution:

Wait for Lambda to complete the initialization process. Lambda launches three instances by default for AZ resiliency and starts three execution environments before marking your function version ACTIVE. This typically takes several minutes.

Cannot delete capacity provider

Problem: You receive an error when attempting to delete a capacity provider.

Cause: You cannot delete a capacity provider that has function versions attached to it.

Solution:

1. Identify all function versions using the capacity provider with the `ListFunctionVersionsByCapacityProvider` API.

2. Delete or update those function versions to remove the capacity provider association.
3. Retry deleting the capacity provider.

Generic error messages during function publishing

Problem: You encounter generic error messages such as "Internal error occurred during publishing" when publishing functions.

Solution:

- **Check IAM permissions:** Ensure you have the `lambda:PassCapacityProvider` permission for the capacity provider you're trying to use.
- **Verify capacity provider configuration:** Confirm that your capacity provider is in the `ACTIVE` state using the `GetCapacityProvider` API.
- **Review VPC configuration:** Ensure the subnets and security groups specified in your capacity provider are correctly configured and accessible.
- **Check AWS CloudTrail logs:** Review CloudTrail logs for detailed error information about the failed operation.

Monitoring and observability issues

Missing CloudWatch metrics

Problem: You don't see expected metrics in CloudWatch for your capacity provider or functions.

Cause: Metrics are published at 5-minute intervals. New capacity providers or functions may not have metrics available immediately.

Solution:

Wait at least 5-10 minutes after publishing a function version before expecting metrics to appear in CloudWatch. Verify you're looking at the correct namespace (`AWS/Lambda`) and dimensions (`CapacityProviderName`, `FunctionName`, or `InstanceType`).

Cannot find CloudWatch logs

Problem: Your function executes successfully, but you cannot find logs in CloudWatch Logs.

Cause: Lambda Managed Instances run in your VPC and require network connectivity to send logs to CloudWatch Logs. Without proper VPC connectivity configuration, your functions cannot reach the CloudWatch Logs service endpoint.

Solution:

Configure VPC connectivity to enable your functions to send logs to CloudWatch Logs. You have three options:

Option 1: VPC endpoint for CloudWatch Logs (recommended for production)

1. Open the Amazon VPC console at console.aws.amazon.com/vpc/.
2. In the navigation pane, choose **Endpoints**.
3. Choose **Create endpoint**.
4. For **Service category**, choose **AWS services**.
5. For **Service name**, select `com.amazonaws.region.logs` (replace `region` with your AWS Region).
6. For **VPC**, select the VPC used by your capacity provider.
7. For **Subnets**, select the subnets where you want to create endpoint network interfaces. For high availability, select subnets in multiple Availability Zones.
8. For **Security groups**, select security groups that allow inbound HTTPS traffic (port 443) from your function's security group.
9. Enable **Private DNS** for the endpoint.
10. Choose **Create endpoint**.

Option 2: Public subnet with internet gateway

If your capacity provider uses public subnets, ensure:

1. An internet gateway is attached to your VPC
2. The route table routes `0.0.0.0/0` traffic to the internet gateway
3. Security groups allow outbound HTTPS traffic on port 443

Option 3: Private subnet with NAT gateway

If your capacity provider uses private subnets, ensure:

1. A NAT gateway exists in a public subnet
2. The private subnet route table routes `0.0.0.0/0` traffic to the NAT gateway
3. The public subnet route table routes `0.0.0.0/0` traffic to an internet gateway
4. Security groups allow outbound HTTPS traffic on port 443

For detailed guidance on VPC connectivity options, see [VPC connectivity for Lambda Managed Instances](#).

Difficulty correlating logs from concurrent requests

Problem: Logs from different requests are interleaved, making it difficult to trace individual requests.

Cause: Log interleaving is expected and standard behavior in multi-concurrent systems.

Solution:

- **Use structured logging with JSON format:** Include request ID in all log statements
- **Java:** Use Log4j with ThreadContext to automatically include request ID
- **Node.js:** Use `console.log()` with JSON formatting and include `InvokeStore.getRequestId()`
- **Python:** Use the standard logging module with JSON formatting and include `context.request_id`

For detailed guidance, see the runtime-specific documentation pages.

Getting additional help

If you continue to experience issues after trying these solutions:

1. **Review CloudWatch metrics:** Check capacity provider and execution environment metrics to identify resource constraints or scaling issues.
2. **Check AWS CloudTrail logs:** Review CloudTrail logs for detailed information about API calls and errors.
3. **Contact AWS Support:** If you cannot resolve the issue, contact AWS Support with details about your capacity provider configuration, function configuration, and the specific error messages you're encountering.

Next steps

- Learn about [capacity providers for Lambda Managed Instances](#)
- Understand [scaling for Lambda Managed Instances](#)
- Review runtime-specific guides for [Java](#), [Node.js](#), and [Python](#)
- Monitor Lambda Managed Instances with [CloudWatch metrics](#)
- Review [best practices for Lambda Managed Instances](#)

Lambda runtimes

Lambda supports multiple languages through the use of *runtimes*. A runtime provides a language-specific environment that relays invocation events, context information, and responses between Lambda and the function. You can use runtimes that Lambda provides, or build your own.

Lambda is agnostic to your choice of runtime. For simple functions, interpreted languages like Python and Node.js offer the fastest performance. For functions with more complex computation, compiled languages like Java are often slower to initialize but run quickly in the Lambda handler. Choice of runtime is also influenced by developer preference and language familiarity.

Each major programming language release has a separate runtime, with a unique *runtime identifier*, such as `nodejs24.x` or `python3.14`. To configure a function to use a new major language version, you need to change the runtime identifier. Since AWS Lambda cannot guarantee backward compatibility between major versions, this is a customer-driven operation.

For a [function defined as a container image](#), you choose a runtime and the Linux distribution when you create the container image. To change the runtime, you create a new container image.

When you use a .zip file archive for the deployment package, you choose a runtime when you create the function. To change the runtime, you can [update your function's configuration](#). The runtime is paired with one of the Amazon Linux distributions. The underlying execution environment provides additional libraries and [environment variables](#) that you can access from your function code.

Lambda invokes your function in an [execution environment](#). The execution environment provides a secure and isolated runtime environment that manages the resources required to run your function. Lambda re-uses the execution environment from a previous invocation if one is available, or it can create a new execution environment.

To use other languages in Lambda, such as [Go](#) or [Rust](#), use an [OS-only runtime](#). The Lambda execution environment provides a [runtime interface](#) for getting invocation events and sending responses. You can deploy other languages by implementing a [custom runtime](#) alongside your function code, or in a [layer](#).

Supported runtimes

The following table lists the supported Lambda runtimes and projected deprecation dates. After a runtime is deprecated, you're still able to create and update functions for a limited period. For

more information, see [the section called “Runtime use after deprecation”](#). The table provides the currently forecasted dates for runtime deprecation, based on our [the section called “Runtime deprecation policy”](#). These dates are provided for planning purposes and are subject to change.

Important

Amazon Linux 2 is scheduled for end of life on June 30, 2026. Lambda runtimes and container base images for Java 8 (AL2), Java 11, Java 17, Python 3.10, Python 3.11, and provided.al2 will continue to receive patches for [critical and selected important](#) Amazon Linux 2 security issues, in addition to language runtime patches, until the deprecation dates shown in the table below.

We recommend customers upgrade to an Amazon Linux 2023-based runtime as soon as possible. For customers upgrading to Java 21 or Java 25, you can use [AWS Transform custom](#) to assist with these upgrades. For customers unable to upgrade their Java version, we plan to release Amazon Linux 2023-based runtimes for Java 8, Java 11, and Java 17 before the end of Q2 2026.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update

OS-only Runtime	provided.al2	Amazon Linux 2	Jul 31, 2026	Aug 31, 2026	Sep 30, 2026

Note

For new regions, Lambda will not support runtimes that are set to be deprecated within the next 6 months.

Lambda keeps managed runtimes and their corresponding container base images up to date with patches and support for minor version releases. For more information see [Lambda runtime updates](#).

To programmatically interact with other AWS services and resources from your Lambda function, you can use one of AWS SDKs. The Node.js, Python, and Ruby runtimes include a version of the AWS SDK. However, to maintain full control of your dependencies, and to maximize [backward compatibility](#) during automatic runtime updates, we recommend that you always include the SDK modules your code uses (along with any dependencies) in your function's deployment package or in a [Lambda layer](#).

We recommend that you use the runtime-included SDK version only when you can't include additional packages in your deployment. For example, when you create your function using the Lambda console code editor or using inline function code in an CloudFormation template.

Lambda periodically updates the versions of the AWS SDKs included in the Node.js, Python, and Ruby runtimes. To determine the version of the AWS SDK included in the runtime you're using, see the following sections:

- [Runtime-included SDK versions \(Node.js\)](#)
- [Runtime-included SDK versions \(Python\)](#)
- [Runtime-included SDK versions \(Ruby\)](#)

Lambda continues to support the Go programming language after deprecation of the Go 1.x runtime. For more information, see [Migrating AWS Lambda functions from the Go1.x runtime to the custom runtime on Amazon Linux 2](#) on the *AWS Compute Blog*.

All supported Lambda runtimes support both x86_64 and arm64 architectures.

New runtime releases

Lambda provides managed runtimes for new language versions only when the release reaches the long-term support (LTS) phase of the language's release cycle. For example, for the [Node.js release cycle](#), when the release reaches the Active LTS phase.

Before the release reaches the long-term support phase, it remains in development and can still be subject to breaking changes. Lambda applies runtime updates automatically by default, so breaking changes to a runtime version could stop your functions from working as expected.

Lambda doesn't provide managed runtimes for language versions which aren't scheduled for LTS release.

The following list shows the target launch month for upcoming Lambda runtimes. These dates are indicative only and subject to change.

- **Ruby 3.5** - March 2026
- **Java 8, 11, and 17 on AL2023** - Q2 2026
- **Node.js 26** - November 2026
- **Python 3.15** - November 2026

Runtime deprecation policy

Lambda runtimes for .zip file archives are built around a combination of operating system, programming language, and software libraries that are subject to maintenance and security updates. Lambda's standard deprecation policy is to deprecate a runtime when any major component of the runtime reaches the end of community long-term support (LTS) and security updates are no longer available. Most usually, this is the language runtime, though in some cases, a runtime can be deprecated because the operating system (OS) reaches end of LTS.

After a runtime is deprecated, AWS may no longer apply security patches or updates to that runtime, and functions using that runtime are no longer eligible for technical support. Such deprecated runtimes are provided 'as-is', without any warranties, and may contain bugs, errors, defects, or other vulnerabilities.

To learn more about managing runtime upgrades and deprecation, see the following sections and [Managing AWS Lambda runtime upgrades](#) on the *AWS Compute Blog*.

Important

Lambda occasionally delays deprecation of a Lambda runtime for a limited period beyond the end of support date of the language version that the runtime supports. During this period, Lambda only applies security patches to the runtime OS. Lambda doesn't apply security patches to programming language runtimes after they reach their end of support date.

Shared responsibility model

Lambda is responsible for curating and publishing security updates for all supported managed runtimes and container base images. By default, Lambda will apply these updates automatically to functions using managed runtimes. Where the default automatic runtime update setting has been changed, see the [runtime management controls shared responsibility model](#). For functions deployed using container images, you're responsible for rebuilding your function's container image from the latest base image and redeploying the container image.

When a runtime is deprecated, Lambda's responsibility for updating the managed runtime and container base images ceases. You are responsible for upgrading your functions to use a supported runtime or base image.

In all cases, you are responsible for applying updates to your function code, including its dependencies. Your responsibilities under the shared responsibility model are summarized in the following table.

Runtime lifecycle phase	Lambda's responsibilities	Your responsibilities
Supported managed runtime	<p>Provide regular runtime updates with security patches and other updates.</p> <p>Apply runtime updates automatically by default (see the section called "Runtime update modes" for non-default behaviors).</p>	Update your function code, including dependencies, to address any security vulnerabilities.
Supported container image	Provide regular updates to container base image with security patches and other updates.	<p>Update your function code, including dependencies, to address any security vulnerabilities.</p> <p>Regularly re-build and re-deploy your container image using the latest base image.</p>
Managed runtime approaching deprecation	<p>Notify customers prior to runtime deprecation via documentation, Health Dashboard, email, and Trusted Advisor.</p> <p>Responsibility for runtime updates ends at deprecation.</p>	<p>Monitor Lambda documentation, Health Dashboard, email, or Trusted Advisor for runtime deprecation information.</p> <p>Upgrade functions to a supported runtime before the previous runtime is deprecated.</p>
Container image approaching deprecation	Deprecation notifications are not available for functions using container images.	Be aware of deprecation schedules and upgrade functions to a supported base

Runtime lifecycle phase	Lambda's responsibilities	Your responsibilities
	Responsibility for container base image updates ends at deprecation.	image before the previous image is deprecated.

Runtime use after deprecation

After a runtime is deprecated, AWS may no longer apply security patches or updates to that runtime, and functions using that runtime are no longer eligible for technical support. While you can continue to invoke your functions indefinitely, AWS strongly recommends migrating to a supported runtime. Deprecated runtimes are provided 'as-is', without any warranties, and may contain bugs, errors, defects, or other vulnerabilities. Functions that use a deprecated runtime may also experience degraded performance or other issues, such as a certificate expiry, that can cause them to stop working properly.

You can update a function to use a newer supported runtime at any time after a runtime is deprecated. We recommend testing your function with the new runtime before applying changes in production environments. You will not be able to revert to the deprecated runtime after function updates are blocked. We recommend using function [versions](#) and [aliases](#) to enable safe deployment with rollback.

The following timeline describes what happens when a runtime is deprecated:

Runtime lifecycle phase	When	What
Deprecation notice period	At least 180 days before deprecation	<ul style="list-style-type: none">AWS sends notifications through email and the Health Dashboard to accounts that have functions using this runtime in their \$LATEST version.Affected functions are also listed in the Health Dashboard Scheduled changes tab and the AWS Trusted Advisor deprecated runtimes check.

Runtime lifecycle phase	When	What
Deprecation	Deprecation date	<ul style="list-style-type: none"> • AWS may no longer apply security updates or other updates. • Functions are no longer eligible for technical support. • You can no longer create or update functions using the deprecated runtime in the Lambda console. You can continue to create and update functions through the AWS CLI, AWS SAM, or CloudFormation.
Block function create	At least 30 days after deprecation	<ul style="list-style-type: none"> • Lambda begins blocking creation of new functions. • You can continue to update code and configuration for existing functions through the AWS CLI, AWS SAM, or CloudFormation..
Block function update	At least 60 days after deprecation	<ul style="list-style-type: none"> • Lambda begins blocking the update of code and configuration for existing functions. • You can still upgrade the function configuration to a supported runtime. However, rolling back to the deprecated runtime may be blocked.

Note

For some runtimes, AWS is delaying the block-function-create and block-function-update dates beyond the usual 30 and 60 days after deprecation. AWS has made this change in response to customer feedback to give you more time to upgrade your functions. Refer to the tables in [the section called “Supported runtimes”](#) and [the section called “Deprecated runtimes”](#) to see the dates for your runtime. Lambda will not start blocking function creates or updates before the dates given in these tables.

Receiving runtime deprecation notifications

When a runtime approaches its deprecation date, Lambda sends you an email alert if any functions in your AWS account use that runtime. Notifications are also displayed in the Health Dashboard and in AWS Trusted Advisor.

- Receiving email notifications:

Lambda sends you an email alert at least **180 days** before a runtime is deprecated. This email lists the **\$LATEST** versions of all functions using the runtime. To see a full list of affected function versions, use Trusted Advisor or see [the section called “Get data about functions by runtime”](#).

Lambda sends email notification to your AWS account's primary account contact. For information about viewing or updating the email addresses in your account, see [Updating contact information](#) in the *AWS General Reference*.

- Receiving notifications through the Health Dashboard:

The Health Dashboard displays a notification at least **180 days** before a runtime is deprecated. Notifications appear on the **Your account health** page under [Other notifications](#). The **Affected resources** tab of the notification lists the **\$LATEST** versions of all functions using the runtime.

Note

To see a full and up-to-date list of affected function versions, use Trusted Advisor or see [the section called “Get data about functions by runtime”](#).

Health Dashboard notifications expire 90 days after the affected runtime is deprecated.

- Using AWS Trusted Advisor

Trusted Advisor displays a notification at least **180 days** before a runtime is deprecated. Notifications appear on the [Security](#) page. A list of your affected functions is displayed under **AWS Lambda Functions Using Deprecated Runtimes**. This list of functions shows both **\$LATEST** and published versions and updates automatically to reflect your functions' current status.

You can turn on weekly email notifications from Trusted Advisor in the [Preferences](#) page of the Trusted Advisor console.

Deprecated runtimes

The following runtimes have reached end of support:

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update

In almost all cases, the end-of-life date of a language version or operating system is known well in advance. The following links give end-of-life schedules for each language that Lambda supports as a managed runtime.

Language and framework support policies

- **Node.js** – github.com
- **Python** – devguide.python.org
- **Ruby** – www.ruby-lang.org
- **Java** – www.oracle.com and [Corretto FAQs](#)
- **Go** – golang.org
- **.NET** – dotnet.microsoft.com

Understanding how Lambda manages runtime version updates

Lambda keeps each managed runtime up to date with security updates, bug fixes, new features, performance enhancements, and support for minor version releases. These runtime updates are published as *runtime versions*. Lambda applies runtime updates to functions by migrating the function from an earlier runtime version to a new runtime version.

By default, for functions using managed runtimes, Lambda applies runtime updates automatically. With automatic runtime updates, Lambda takes on the operational burden of patching the runtime versions. For most customers, automatic updates are the right choice. You can change this default behavior by [configuring runtime management settings](#).

Lambda also publishes each new runtime version as a container image. To update runtime versions for container-based functions, you must [create a new container image](#) from the updated base image and redeploy your function.

Each runtime version is associated with a version number and an ARN (Amazon Resource Name). Runtime version numbers use a numbering scheme that Lambda defines, independent of the version numbers that the programming language uses. Runtime version numbers are not always sequential. For example, version 42 might be followed by version 45. The runtime version ARN is a unique identifier for each runtime version. You can view the ARN of your function's current runtime version in the Lambda console, or the [INIT_START line of your function logs](#).

Runtime versions should not be confused with runtime identifiers. Each runtime has a unique **runtime identifier**, such as `python3.14` or `nodejs24.x`. These correspond to each major programming language release. Runtime versions describe the patch version of an individual runtime.

Note

The ARN for the same runtime version number can vary between AWS Regions and CPU architectures.

Backward compatibility

Lambda strives to provide runtime updates that are backward compatible with existing functions. However, as with software patching, there are rare cases in which a runtime update can negatively impact an existing function. For example, security patches can expose an underlying issue with an existing function that depends on the previous, insecure behavior.

When building and deploying your function, it is important to understand how to manage your dependencies to avoid potential incompatibilities with a future runtime update. For example, suppose your function has a dependency on package A, which in turn depends on package B. Both packages are included in the Lambda runtime (for example, they could be parts of the SDK or its dependencies, or parts of the runtime system libraries).

Consider the following scenarios:

Deployment	Patching compatible	Reason
<ul style="list-style-type: none"> • Package A: Use from runtime • Package B: Use from runtime 	Yes	Future runtime updates to packages A and B are backward compatible.
<ul style="list-style-type: none"> • Package A: In deployment package • Package B: In deployment package 	Yes	Your deployment takes precedence, so future runtime updates to packages A and B have no effect.
<ul style="list-style-type: none"> • Package A: In deployment package 	Yes*	Future runtime updates to package B are backward compatible.

Deployment	Patching compatible	Reason
<ul style="list-style-type: none"> Package B: Use from runtime 		*If A and B are tightly coupled, compatibility issues can occur. For example, the boto3 and botocore packages in the AWS SDK for Python should be deployed together.
<ul style="list-style-type: none"> Package A: Use from runtime Package B: In deployment package 	No	Future runtime updates to package A might require an updated version of package B. However, the deployed version of package B takes precedence, and might not be forward compatible with the updated version of package A.

To maintain compatibility with future runtime updates, follow these best practices:

- **When possible, package all dependencies:** Include all required libraries, including the AWS SDK and its dependencies, in your deployment package. This ensures a stable, compatible set of components.
- **Use runtime-provided SDKs sparingly:** Only rely on the runtime-provided SDK when you can't include additional packages (for example, when using the Lambda console code editor or inline code in an AWS CloudFormation template).
- **Avoid overriding system libraries:** Don't deploy custom operating system libraries that may conflict with future runtime updates.

Runtime update modes

Lambda strives to provide runtime updates that are backward compatible with existing functions. However, as with software patching, there are rare cases in which a runtime update can negatively impact an existing function. For example, security patches can expose an underlying issue with an

existing function that depends on the previous, insecure behavior. Lambda runtime management controls help reduce the risk of impact to your workloads in the rare event of a runtime version incompatibility. For each [function version](#) (\$LATEST or published version), you can choose one of the following runtime update modes:

- **Auto (default)** – Automatically update to the most recent and secure runtime version using [Two-phase runtime version rollout](#). We recommend this mode for most customers so that you always benefit from runtime updates.
- **Function update** – Update to the most recent and secure runtime version when you update your function. When you update your function, Lambda updates the runtime of your function to the most recent and secure runtime version. This approach synchronizes runtime updates with function deployments, giving you control over when Lambda applies runtime updates. With this mode, you can detect and mitigate rare runtime update incompatibilities early. When using this mode, you must regularly update your functions to keep their runtime up to date.
- **Manual** – Manually update your runtime version. You specify a runtime version in your function configuration. The function uses this runtime version indefinitely. In the rare case in which a new runtime version is incompatible with an existing function, you can use this mode to roll back your function to an earlier runtime version. We recommend against using **Manual** mode to try to achieve runtime consistency across deployments. For more information, see [Rolling back a Lambda runtime version](#).

Responsibility for applying runtime updates to your functions varies according to which runtime update mode you choose. For more information, see [Understanding the shared responsibility model for Lambda runtime management](#).

Two-phase runtime version rollout

Lambda introduces new runtime versions in the following order:

1. In the first phase, Lambda applies the new runtime version whenever you create or update a function. A function gets updated when you call the [UpdateFunctionCode](#) or [UpdateFunctionConfiguration](#) API operations.
2. In the second phase, Lambda updates any function that uses the **Auto** runtime update mode and that hasn't already been updated to the new runtime version.

The overall duration of the rollout process varies according to multiple factors, including the severity of any security patches included in the runtime update.

If you're actively developing and deploying your functions, you will most likely pick up new runtime versions during the first phase. This synchronizes runtime updates with function updates. In the rare event that the latest runtime version negatively impacts your application, this approach lets you take prompt corrective action. Functions that aren't in active development still receive the operational benefit of automatic runtime updates during the second phase.

This approach doesn't affect functions set to **Function update** or **Manual** mode. Functions using **Function update** mode receive the latest runtime updates only when you create or update them. Functions using **Manual** mode don't receive runtime updates.

Lambda publishes new runtime versions in a gradual, rolling fashion across AWS Regions. If your functions are set to **Auto** or **Function update** modes, it's possible that functions deployed at the same time to different Regions, or at different times in the same Region, will pick up different runtime versions. Customers who require guaranteed runtime version consistency across their environments should [use container images to deploy their Lambda functions](#). The **Manual** mode is designed as a temporary mitigation to enable runtime version rollback in the rare event that a runtime version is incompatible with your function.

Configuring Lambda runtime management settings

You can configure runtime management settings using the Lambda console or the AWS Command Line Interface (AWS CLI).

Note

You can configure runtime management settings separately for each [function version](#).

To configure how Lambda updates your runtime version (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of a function.
3. On the **Code** tab, under **Runtime settings**, choose **Edit runtime management configuration**.
4. Under **Runtime management configuration**, choose one of the following:
 - To have your function update to the latest runtime version automatically, choose **Auto**.

- To have your function update to the latest runtime version when you change the function, choose **Function update**.
- To have your function update to the latest runtime version only when you change the runtime version ARN, choose **Manual**. You can find the runtime version ARN under **Runtime management configuration**. You can also find the ARN in the INIT_START line of your function logs.

For more information about these options, see [Runtime update modes](#).

5. Choose **Save**.

To configure how Lambda updates your runtime version (AWS CLI)

To configure runtime management for a function, run the [put-runtime-management-config](#) AWS CLI command. When using Manual mode, you must also provide the runtime version ARN.

```
aws lambda put-runtime-management-config \  
  --function-name my-function \  
  --update-runtime-on Manual \  
  --runtime-version-arn arn:aws:lambda:us-east-2::runtime:8eeff65f6809a3ce81507fe733fe09b835899b99481ba22fd75b5a7338290ec1
```

You should see output similar to the following:

```
{  
  "UpdateRuntimeOn": "Manual",  
  "FunctionArn": "arn:aws:lambda:us-east-2:111122223333:function:my-function",  
  "RuntimeVersionArn": "arn:aws:lambda:us-east-2::runtime:8eeff65f6809a3ce81507fe733fe09b835899b99481ba22fd75b5a7338290ec1"  
}
```

Rolling back a Lambda runtime version

In the rare event that a new runtime version is incompatible with your existing function, you can roll back its runtime version to an earlier one. This keeps your application working and minimizes disruption, providing time to remedy the incompatibility before returning to the latest runtime version.

Lambda doesn't impose a time limit on how long you can use any particular runtime version. However, we strongly recommend updating to the latest runtime version as soon as possible to benefit from the latest security patches, performance improvements, and features. Lambda provides the option to roll back to an earlier runtime version only as a temporary mitigation in the rare event of a runtime update compatibility issue. Functions using an earlier runtime version for an extended period may eventually experience degraded performance or issues, such as a certificate expiry, which can cause them to stop working properly.

You can roll back a runtime version in the following ways:

- [Using the Manual runtime update mode](#)
- [Using published function versions](#)

For more information, see [Introducing AWS Lambda runtime management controls](#) on the AWS Compute Blog.

Roll back a runtime version using Manual runtime update mode

If you're using the **Auto** runtime version update mode, or you're using the `$LATEST` runtime version, you can roll back your runtime version using the **Manual** mode. For the [function version](#) you want to roll back, change the runtime version update mode to **Manual** and specify the ARN of the previous runtime version. For more information about finding the ARN of the previous runtime version, see [Identifying Lambda runtime version changes](#).

Note

If the `$LATEST` version of your function is configured to use **Manual** mode, then you can't change the CPU architecture or runtime version that your function uses. To make these changes, you must change to **Auto** or **Function update** mode.

Roll back a runtime version using published function versions

Published [function versions](#) are an immutable snapshot of the `$LATEST` function code and configuration at the time that you created them. In **Auto** mode, Lambda automatically updates the runtime version of published function versions during phase two of the runtime version rollout. In **Function update** mode, Lambda doesn't update the runtime version of published function versions.

Published function versions using **Function update** mode therefore create a static snapshot of the function code, configuration, and runtime version. By using **Function update** mode with function versions, you can synchronize runtime updates with your deployments. You can also coordinate rollback of code, configuration, and runtime versions by redirecting traffic to an earlier published function version. You can integrate this approach into your continuous integration and continuous delivery (CI/CD) for fully automatic rollback in the rare event of runtime update incompatibility. When using this approach, you must update your function regularly and publish new function versions to pick up the latest runtime updates. For more information, see [Understanding the shared responsibility model for Lambda runtime management](#).

Identifying Lambda runtime version changes

The [runtime version number](#) and ARN are logged in the INIT_START log line, which Lambda emits to CloudWatch Logs each time that it creates a new [execution environment](#). Because the execution environment uses the same runtime version for all function invocations, Lambda emits the INIT_START log line only when Lambda executes the init phase. Lambda doesn't emit this log line for each function invocation. Lambda emits the log line to CloudWatch Logs, but it is not visible in the console.

Note

Runtime version numbers are not always sequential. For example, version 42 might be followed by version 45.

Example INIT_START log line

```
INIT_START Runtime Version: python:3.13.v14    Runtime Version ARN: arn:aws:lambda:eu-south-1::runtime:7b620fc2e66107a1046b140b9d320295811af3ad5d4c6a011fad1fa65127e9e6I
```

Rather than working directly with the logs, you can use [Amazon CloudWatch Contributor Insights](#) to identify transitions between runtime versions. The following rule counts the distinct runtime versions from each INIT_START log line. To use the rule, replace the example log group name `/aws/lambda/*` with the appropriate prefix for your function or group of functions.

```
{
  "Schema": {
    "Name": "CloudWatchLogRule",
```

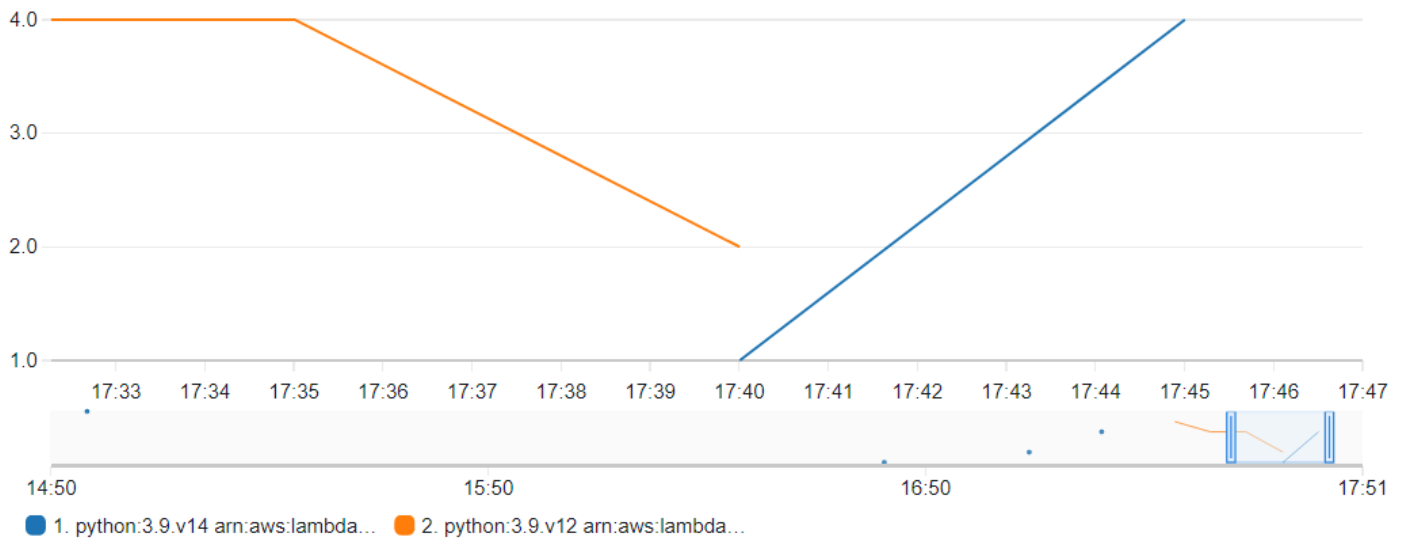

```
    "Version": 1
  },
  "AggregateOn": "Count",
  "Contribution": {
    "Filters": [
      {
        "Match": "eventType",
        "In": [
          "INIT_START"
        ]
      }
    ],
    "Keys": [
      "runtimeVersion",
      "runtimeVersionArn"
    ]
  },
  "LogFormat": "CLF",
  "LogGroupNames": [
    "/aws/lambda/*"
  ],
  "Fields": {
    "1": "eventType",
    "4": "runtimeVersion",
    "8": "runtimeVersionArn"
  }
}
```

The following CloudWatch Contributor Insights report shows an example of a runtime version transition as captured by the preceding rule. The orange line shows execution environment initialization for the earlier runtime version (**python:3.13.v12**), and the blue line shows execution environment initialization for the new runtime version (**python:3.13.v14**).

Understanding the shared responsibility model for Lambda runtime management

Lambda is responsible for curating and publishing security updates for all supported managed runtimes and container images. Responsibility for updating existing functions to use the latest runtime version varies depending on which runtime update mode you use.

Lambda is responsible for applying runtime updates to all functions configured to use the **Auto** runtime update mode.

For functions configured with the **Function update** runtime update mode, you're responsible for regularly updating your function. Lambda is responsible for applying runtime updates when you make those updates. If you don't update your function, then Lambda doesn't update the runtime. If you don't regularly update your function, then we strongly recommend configuring it for automatic runtime updates so that it continues to receive security updates.

For functions configured to use the **Manual** runtime update mode, you're responsible for updating your function to use the latest runtime version. We strongly recommend that you use this mode only to roll back the runtime version as a temporary mitigation in the rare event of runtime update incompatibility. We also recommend that you change to **Auto** mode as quickly as possible to minimize the time in which your functions aren't patched.

If you're [using container images to deploy your functions](#), then Lambda is responsible for publishing updated base images. In this case, you're responsible for rebuilding your function's container image from the latest base image and redeploying the container image.

This is summarized in the following table:

Deployment mode	Lambda's responsibility	Customer's responsibility
Managed runtime, Auto mode	Publish new runtime versions containing the latest patches. Apply runtime patches to existing functions.	Roll back to a previous runtime version in the rare event of a runtime update compatibility issue. Follow best practices for backward compatibility .
Managed runtime, Function update mode	Publish new runtime versions containing the latest patches.	Update functions regularly to pick up the latest runtime version. Switch a function to Auto mode when you're not regularly updating the function. Roll back to a previous runtime version in the rare event of a runtime update compatibility issue. Follow best practices for backward compatibility .
Managed runtime, Manual mode	Publish new runtime versions containing the latest patches.	Use this mode only for temporary runtime rollback in the rare event of a runtime update compatibility issue. Switch functions to Auto or Function update mode and the latest runtime version as soon as possible.
Container image	Publish new container images containing the latest patches.	Redeploy functions regularly using the latest container base image to pick up the latest patches.

For more information about shared responsibility with AWS, see [Shared Responsibility Model](#).

Controlling Lambda runtime update permissions for high-compliance applications

To meet patching requirements, Lambda customers typically rely on automatic runtime updates. If your application is subject to strict patching freshness requirements, you may want to limit use of earlier runtime versions. You can restrict Lambda's runtime management controls by using AWS Identity and Access Management (IAM) to deny users in your AWS account access to the [PutRuntimeManagementConfig](#) API operation. This operation is used to choose the runtime update mode for a function. Denying access to this operation causes all functions to default to the **Auto** mode. You can apply this restriction across your organization by using a [service control policies \(SCP\)](#). If you must roll back a function to an earlier runtime version, you can grant a policy exception on a case-by-case basis.

Retrieve data about Lambda functions that use a deprecated runtime

When a Lambda runtime is approaching deprecation, Lambda alerts you through email and provides notifications in the Health Dashboard and Trusted Advisor. These emails and notifications list the `$LATEST` versions of functions using the runtime. To list all of your function versions that use a particular runtime, you can use the AWS Command Line Interface (AWS CLI) or one of the AWS SDKs.

If you have a large number of functions which use a runtime that is due to be deprecated, you can also use the AWS CLI or AWS SDKs to help you prioritize updates to your most commonly invoked functions.

Refer to the following sections to learn how to use the AWS CLI and AWS SDKs to gather data about functions that use a particular runtime.

Listing function versions that use a particular runtime

To use the AWS CLI to list all of your function versions that use a particular runtime, run the following command. Replace `RUNTIME_IDENTIFIER` with the name of the runtime that's being deprecated and choose your own AWS Region. To list only `$LATEST` function versions, omit `--function-version ALL` from the command.

```
aws lambda list-functions --function-version ALL --region us-east-1 --output text --  
query "Functions[?Runtime=='RUNTIME_IDENTIFIER'].FunctionArn"
```

Tip

The example command lists functions in the `us-east-1` region for a particular AWS account. You'll need to repeat this command for each region in which your account has functions and for each of your AWS accounts.

You can also list functions that use a particular runtime using one of the AWS SDKs. The following example code uses the V3 AWS SDK for JavaScript and the AWS SDK for Python (Boto3) to return a list of the function ARNs for functions using a particular runtime. The example code also returns the CloudWatch log group for each of the listed functions. You can use this log group to find the

last invocation date for the function. See the following section [the section called “Identifying most commonly and most recently invoked functions”](#) for more information.

Node.js

Example JavaScript code to list functions using a particular runtime

```
import { LambdaClient, ListFunctionsCommand } from "@aws-sdk/client-lambda";
const lambdaClient = new LambdaClient();

const command = new ListFunctionsCommand({
  FunctionVersion: "ALL",
  MaxItems: 50
});
const response = await lambdaClient.send(command);

for (const f of response.Functions){
  if (f.Runtime == '<your_runtime>'){ // Use the runtime id, e.g. 'nodejs24.x' or
    'python3.14'
    console.log(f.FunctionArn);
    // get the CloudWatch log group of the function to
    // use later for finding the last invocation date
    console.log(f.LoggingConfig.LogGroup);
  }
}
// If your account has more functions than the specified
// MaxItems, use the returned pagination token in the
// next request with the 'Marker' parameter
if ('NextMarker' in response){
  let paginationToken = response.NextMarker;
}
```

Python

Example Python code to list functions using a particular runtime

```
import boto3
from botocore.exceptions import ClientError

def list_lambda_functions(target_runtime):

    lambda_client = boto3.client('lambda')
```

```
response = lambda_client.list_functions(
    FunctionVersion='ALL',
    MaxItems=50
)
if not response['Functions']:
    print("No Lambda functions found")
else:
    for function in response['Functions']:
        if function['PackageType']=='Zip' and function['Runtime'] ==
target_runtime:
            print(function['FunctionArn'])
            # Print the CloudWatch log group of the function
            # to use later for finding last invocation date
            print(function['LoggingConfig']['LogGroup'])

    if 'NextMarker' in response:
        pagination_token = response['NextMarker']

if __name__ == "__main__":
    # Replace python3.12 with the appropriate runtime ID for your Lambda functions
    list_lambda_functions('python3.12')
```

To learn more about using an AWS SDK to list your functions using the [ListFunctions](#) action, see the [SDK documentation](#) for your preferred programming language.

You can also use the AWS Config Advanced queries feature to list all your functions that use an affected runtime. This query only returns function \$LATEST versions, but you can aggregate queries to list function across all regions and multiple AWS accounts with a single command. To learn more, see [Querying the Current Configuration State of AWS Auto Scaling Resources](#) in the *AWS Config Developer Guide*.

Identifying most commonly and most recently invoked functions

If your AWS account contains functions that use a runtime that's due to be deprecated, you might want to prioritize updating functions that are frequently invoked or functions that have been invoked recently.

If you have only a few functions, you can use the CloudWatch Logs console to gather this information by looking at your functions' log streams. See [View log data sent to CloudWatch Logs](#) for more information.

To see the number of recent function invocations, you can also use the CloudWatch metrics information shown in the Lambda console. To view this information, do the following:

1. Open the [Functions page](#) of the Lambda console.
2. Select the function you want to see invocation statistics for.
3. Choose the **Monitor** tab.
4. Set the time period you wish to view statistics for using the date range picker. Recent invocations are displayed in the **Invocations** pane.

For accounts with larger numbers of functions, it can be more efficient to gather this data programmatically using the AWS CLI or one of the AWS SDKs using the [DescribeLogStreams](#) and [GetMetricStatistics](#) API actions.

The following examples provide code snippets using the V3 AWS SDK for JavaScript and the AWS SDK for Python (Boto3) to identify the last invoke date for a particular function and to determine the number of invocations for a particular function in the last 14 days.

Node.js

Example JavaScript code to find last invocation time for a function

```
import { CloudWatchLogsClient, DescribeLogStreamsCommand } from "@aws-sdk/client-cloudwatch-logs";
const cloudWatchLogsClient = new CloudWatchLogsClient();
const command = new DescribeLogStreamsCommand({
  logGroupName: '<your_log_group_name>',
  orderBy: 'LastEventTime',
  descending: true,
  limit: 1
});
try {
  const response = await cloudWatchLogsClient.send(command);
  const lastEventTimestamp = response.logStreams.length > 0 ?
    response.logStreams[0].lastEventTimestamp : null;
  // Convert the UNIX timestamp to a human-readable format for display
  const date = new Date(lastEventTimestamp).toLocaleDateString();
  const time = new Date(lastEventTimestamp).toLocaleTimeString();
  console.log(`${date} ${time}`);
} catch (e){
  console.error('Log group not found.')
```

```
}
```

Python

Example Python code to find last invocation time for a function

```
import boto3
from datetime import datetime

cloudwatch_logs_client = boto3.client('logs')

response = cloudwatch_logs_client.describe_log_streams(
    logGroupName='<your_log_group_name>',
    orderBy='LastEventTime',
    descending=True,
    limit=1
)

try:
    if len(response['logStreams']) > 0:
        last_event_timestamp = response['logStreams'][0]['lastEventTimestamp']
        print(datetime.fromtimestamp(last_event_timestamp/1000)) # Convert timestamp
        # from ms to seconds
    else:
        last_event_timestamp = None
except:
    print('Log group not found')
```

Tip

You can find your function's log group name using the [ListFunctions](#) API operation. See the code in [the section called "Listing function versions that use a particular runtime"](#) for an example of how to do this.

Node.js

Example JavaScript code to find number of invocations in last 14 days

```
import { CloudWatchClient, GetMetricStatisticsCommand } from "@aws-sdk/client-cloudwatch";
```

```

const cloudWatchClient = new CloudWatchClient();
const command = new GetMetricStatisticsCommand({
  Namespace: 'AWS/Lambda',
  MetricName: 'Invocations',
  StartTime: new Date(Date.now()-86400*1000*14), // 14 days ago
  EndTime: new Date(Date.now()),
  Period: 86400 * 14, // 14 days.
  Statistics: ['Sum'],
  Dimensions: [{
    Name: 'FunctionName',
    Value: '<your_function_name>'
  }]
});
const response = await cloudWatchClient.send(command);
const invokesInLast14Days = response.Datapoints.length > 0 ?
  response.Datapoints[0].Sum : 0;

console.log('Number of invocations: ' + invokesInLast14Days);

```

Python

Example Python code to find number of invocations in last 14 days

```

import boto3
from datetime import datetime, timedelta

cloudwatch_client = boto3.client('cloudwatch')

response = cloudwatch_client.get_metric_statistics(
    Namespace='AWS/Lambda',
    MetricName='Invocations',
    Dimensions=[
        {
            'Name': 'FunctionName',
            'Value': '<your_function_name>'
        },
    ],
    StartTime=datetime.now() - timedelta(days=14),
    EndTime=datetime.now(),
    Period=86400 * 14, # 14 days
    Statistics=[
        'Sum'
    ]
)

```

```
)

if len(response['Datapoints']) > 0:
    invokes_in_last_14_days = int(response['Datapoints'][0]['Sum'])
else:
    invokes_in_last_14_days = 0

print(f'Number of invocations: {invokes_in_last_14_days}')
```

Modifying the runtime environment

You can use [internal extensions](#) to modify the runtime process. Internal extensions are not separate processes—they run as part of the runtime process.

Lambda provides language-specific [environment variables](#) that you can set to add options and tools to the runtime. Lambda also provides [wrapper scripts](#), which allow Lambda to delegate the runtime startup to your script. You can create a wrapper script to customize the runtime startup behavior.

Language-specific environment variables

Lambda supports configuration-only ways to enable code to be pre-loaded during function initialization through the following language-specific environment variables:

- `JAVA_TOOL_OPTIONS` – On Java, Lambda supports this environment variable to set additional command-line variables in Lambda. This environment variable allows you to specify the initialization of tools, specifically the launching of native or Java programming language agents using the `agentlib` or `javaagent` options. For more information, see [JAVA_TOOL_OPTIONS environment variable](#).
- `NODE_OPTIONS` – Available in [Node.js runtimes](#).
- `DOTNET_STARTUP_HOOKS` – On .NET Core 3.1 and above, this environment variable specifies a path to an assembly (dll) that Lambda can use.

Using language-specific environment variables is the preferred way to set startup properties.

Wrapper scripts

You can create a *wrapper script* to customize the runtime startup behavior of your Lambda function. A wrapper script enables you to set configuration parameters that cannot be set through language-specific environment variables.

Note

Invocations may fail if the wrapper script does not successfully start the runtime process.

Wrapper scripts are supported on all native [Lambda runtimes](#). Wrapper scripts are not supported on [OS-only runtimes](#) (the provided runtime family).

When you use a wrapper script for your function, Lambda starts the runtime using your script. Lambda sends to your script the path to the interpreter and all of the original arguments for the standard runtime startup. Your script can extend or transform the startup behavior of the program. For example, the script can inject and alter arguments, set environment variables, or capture metrics, errors, and other diagnostic information.

You specify the script by setting the value of the `AWS_LAMBDA_EXEC_WRAPPER` environment variable as the file system path of an executable binary or script.

Example: Create and use a wrapper script as a Lambda layer

In the following example, you create a wrapper script to start the Python interpreter with the `-X importtime` option. When you run the function, Lambda generates a log entry to show the duration of the import time for each import.

To create and use a wrapper script as a layer

1. Create a directory for the layer:

```
mkdir -p python-wrapper-layer/bin  
cd python-wrapper-layer/bin
```

2. In the `bin` directory, paste the following code into a new file named `importtime_wrapper`. This is the wrapper script.

```
#!/bin/bash  
  
# the path to the interpreter and all of the originally intended arguments  
args=("$@")  
  
# the extra options to pass to the interpreter  
extra_args=("-X" "importtime")  
  
# insert the extra options  
args=("${args[@]:0:$#-1}" "${extra_args[@]}" "${args[@]: -1}")  
  
# start the runtime with the extra options  
exec "${args[@]}"
```

3. Give the script executable permissions:

```
chmod +x importtime_wrapper
```

4. Create a .zip file for the layer:

```
cd ..  
zip -r ../python-wrapper-layer.zip .
```

5. Confirm that your .zip file has the following directory structure:

```
python-wrapper-layer.zip  
# bin  
  # importtime_wrapper
```

6. [Create a layer](#) using the .zip package.

7. Create a function using the Lambda console.

- a. Open the [Lambda console](#).
- b. Choose **Create function**.
- c. Enter a **Function name**.
- d. For **Runtime**, choose the **Latest supported** Python runtime.
- e. Choose **Create function**.

8. Add the layer to your function.

- a. Choose your function, and then choose the **Code** tab if it's not already selected.
- b. Scroll down to the **Layers** section, and then choose **Add a layer**.
- c. For **Layer source**, select **Custom layers**, and then choose your layer from the **Custom layers** dropdown list.
- d. For **Version**, choose **1**.
- e. Choose **Add**.

9. Add the wrapper environment variable.

- a. Choose the **Configuration** tab, then choose **Environment variables**.
- b. Under **Environment variables**, choose **Edit**.
- c. Choose **Add environment variable**.
- d. For **Key**, enter `AWS_LAMBDA_EXEC_WRAPPER`.

- e. For **Value**, enter `/opt/bin/importtime_wrapper` (`/opt/` + your `.zip` layer's folder structure).
- f. Choose **Save**.

10. Test the wrapper script.

- a. Choose the **Test** tab.
- b. Under **Test event**, choose **Test**. You don't need to create a test event—the default event will work.
- c. Scroll down to **Log output**. Because your wrapper script started the Python interpreter with the `-X importtime` option, the logs show the time required for each import. For example:

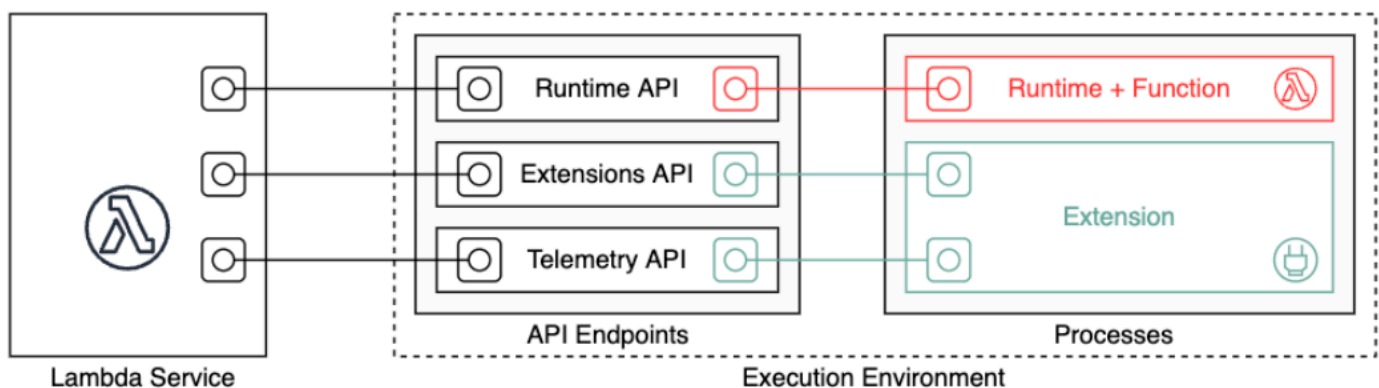

```
532 |          collections
import time:      63 |          63 |          _functools
import time:    1053 |      3646 |          functools
import time:    2163 |      7499 |          enum
import time:     100 |       100 |          _sre
import time:     446 |       446 |          re._constants
import time:     691 |      1136 |          re._parser
import time:     378 |       378 |          re._casefix
import time:     670 |      2283 |          re._compiler
import time:     416 |       416 |          copyreg
```

Using the Lambda runtime API for custom runtimes

AWS Lambda provides an HTTP API for [custom runtimes](#) to receive invocation events from Lambda and send response data back within the Lambda [execution environment](#). This section contains the API reference for the Lambda runtime API.

📘 Lambda Managed Instances support concurrent requests

Lambda Managed Instances use the same runtime API as Lambda (default) functions. The key difference is that Managed Instances can accept concurrent `/next` and `/response` requests up to the configured `AWS_LAMBDA_MAX_CONCURRENCY` limit. This enables multiple invocations to be processed simultaneously within a single execution environment. For more information about Managed Instances, see [Understanding the Lambda Managed Instances execution environment](#).

The OpenAPI specification for the runtime API version **2018-06-01** is available in [runtime-api.zip](#)

To create an API request URL, runtimes get the API endpoint from the `AWS_LAMBDA_RUNTIME_API` environment variable, add the API version, and add the desired resource path.

Example Request

```
curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invocation/next"
```

API methods

- [Next invocation](#)
- [Invocation response](#)
- [Initialization error](#)
- [Invocation error](#)

Next invocation

Path – /runtime/invocation/next

Method – GET

The runtime sends this message to Lambda to request an invocation event. The response body contains the payload from the invocation, which is a JSON document that contains event data from the function trigger. The response headers contain additional data about the invocation.

Response headers

- **Lambda-Runtime-Aws-Request-Id** – The request ID, which identifies the request that triggered the function invocation.

For example, 8476a536-e9f4-11e8-9739-2dfe598c3fcd.

- **Lambda-Runtime-Deadline-Ms** – The date that the function times out in Unix time milliseconds.

For example, 1542409706888.

- **Lambda-Runtime-Invoked-Function-Arn** – The ARN of the Lambda function, version, or alias that's specified in the invocation.

For example, arn:aws:lambda:us-east-2:123456789012:function:custom-runtime.

- **Lambda-Runtime-Trace-Id** – The [AWS X-Ray tracing header](#).

For example, Root=1-5bef4de7-ad49b0e87f6ef6c87fc2e700;Parent=9a9197af755a6419;Sampled=1.

- **Lambda-Runtime-Client-Context** – For invocations from the AWS Mobile SDK, data about the client application and device.
- **Lambda-Runtime-Cognito-Identity** – For invocations from the AWS Mobile SDK, data about the Amazon Cognito identity provider.

Do not set a timeout on the GET request as the response may be delayed. Between when Lambda bootstraps the runtime and when the runtime has an event to return, the runtime process may be frozen for several seconds.

The request ID tracks the invocation within Lambda. Use it to specify the invocation when you send the response.

The tracing header contains the trace ID, parent ID, and sampling decision. If the request is sampled, the request was sampled by Lambda or an upstream service. The runtime should set the `_X_AMZN_TRACE_ID` with the value of the header. The X-Ray SDK reads this to get the IDs and determine whether to trace the request.

Invocation response

Path – `/runtime/invocation/AwsRequestId/response`

Method – POST

After the function has run to completion, the runtime sends an invocation response to Lambda. For synchronous invocations, Lambda sends the response to the client.

Example success request

```
REQUEST_ID=156cb537-e2d4-11e8-9b34-d36013741fb9
curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invocation/$REQUEST_ID/
response" -d "SUCCESS"
```

Initialization error

If the function returns an error or the runtime encounters an error during initialization, the runtime uses this method to report the error to Lambda.

Path – `/runtime/init/error`

Method – POST

Headers

Lambda-Runtime-Function-Error-Type – Error type that the runtime encountered. Required: no.

This header consists of a string value. Lambda accepts any string, but we recommend a format of `<category.reason>`. For example:

- `Runtime.NoSuchHandler`
- `Runtime.APIKeyNotFound`
- `Runtime.ConfigInvalid`
- `Runtime.UnknownReason`

Body parameters

`ErrorRequest` – Information about the error. Required: no.

This field is a JSON object with the following structure:

```
{
    errorMessage: string (text description of the error),
    errorType: string,
    stackTrace: array of strings
}
```

Note that Lambda accepts any value for `errorType`.

The following example shows a Lambda function error message in which the function could not parse the event data provided in the invocation.

Example Function error

```
{
    "errorMessage" : "Error parsing event data.",
    "errorType" : "InvalidEventDataException",
    "stackTrace": [ ]
}
```

Response body parameters

- `StatusResponse` – String. Status information, sent with 202 response codes.
- `ErrorResponse` – Additional error information, sent with the error response codes. `ErrorResponse` contains an error type and an error message.

Response codes

- 202 – Accepted
- 403 – Forbidden
- 500 – Container error. Non-recoverable state. Runtime should exit promptly.

Example initialization error request

```
ERROR="{\"errorMessage\" : \"Failed to load function.\", \"errorType\" :  
  \"InvalidFunctionException\"}"  
curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/init/error" -d "$ERROR" --  
header "Lambda-Runtime-Function-Error-Type: Unhandled"
```

Invocation error

If the function returns an error or the runtime encounters an error, the runtime uses this method to report the error to Lambda.

Path – /runtime/invoke/*AwsRequestId*/error

Method – POST

Headers

Lambda-Runtime-Function-Error-Type – Error type that the runtime encountered. Required: no.

This header consists of a string value. Lambda accepts any string, but we recommend a format of `<category.reason>`. For example:

- Runtime.NoSuchHandler
- Runtime.APIKeyNotFound
- Runtime.ConfigInvalid
- Runtime.UnknownReason

Body parameters

ErrorRequest – Information about the error. Required: no.

This field is a JSON object with the following structure:

```
{
    errorMessage: string (text description of the error),
    errorType: string,
    stackTrace: array of strings
}
```

Note that Lambda accepts any value for `errorType`.

The following example shows a Lambda function error message in which the function could not parse the event data provided in the invocation.

Example Function error

```
{
    "errorMessage" : "Error parsing event data.",
    "errorType" : "InvalidEventDataException",
    "stackTrace": [ ]
}
```

Response body parameters

- `StatusResponse` – String. Status information, sent with 202 response codes.
- `ErrorResponse` – Additional error information, sent with the error response codes. `ErrorResponse` contains an error type and an error message.

Response codes

- 202 – Accepted
- 400 – Bad Request
- 403 – Forbidden
- 500 – Container error. Non-recoverable state. Runtime should exit promptly.

Example error request

```
REQUEST_ID=156cb537-e2d4-11e8-9b34-d36013741fb9
ERROR="{\"errorMessage\" : \"Error parsing event data.\", \"errorType\" :  
  \"InvalidEventDataException\"}"
```

```
curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invoke/$REQUEST_ID/error"  
-d "$ERROR" --header "Lambda-Function-Error-Type: Unhandled"
```

When to use Lambda's OS-only runtimes

Lambda provides [managed runtimes](#) for Java, Python, Node.js, .NET, and Ruby. To create Lambda functions in a programming language that is not available as a managed runtime, use an OS-only runtime (the provided runtime family). There are three primary use cases for OS-only runtimes:

- **Native ahead-of-time (AOT) compilation:** Languages such as Go, Rust, Swift, and C++ compile natively to an executable binary, which doesn't require a dedicated language runtime. These languages only need an OS environment in which the compiled binary can run. You can also use Lambda OS-only runtimes to deploy binaries compiled with .NET Native AOT and Java GraalVM Native Image.

You must include a runtime interface client in your binary. The runtime interface client calls the [Using the Lambda runtime API for custom runtimes](#) to retrieve function invocations and then calls your function handler. Lambda provides runtime interface clients for [Rust](#), [Go](#), [.NET Native AOT](#), [Swift](#) (experimental), and [C++](#) (experimental).

You must compile your binary for a Linux environment and for the same instruction set architecture that you plan to use for the function (x86_64 or arm64).

- **Third-party runtimes:** You can run Lambda functions using off-the-shelf runtimes such as [Bref](#) for PHP.
- **Custom runtimes:** You can build your own runtime for a language or language version that Lambda doesn't provide a managed runtime for, such as Node.js 19. For more information, see [Building a custom runtime for AWS Lambda](#). This is the least common use case for OS-only runtimes.

Lambda supports the following OS-only runtimes:

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
OS-only Runtime	provided.al2023	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
OS-only Runtime	provided.al2	Amazon Linux 2	Jul 31, 2026	Aug 31, 2026	Sep 30, 2026

The Amazon Linux 2023 (provided.al2023) runtime provides several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as glibc.

The provided.al2023 runtime uses dnf as the package manager instead of yum, which is the default package manager in Amazon Linux 2. For more information about the differences between provided.al2023 and provided.al2, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

Building a custom runtime for AWS Lambda

You can implement an AWS Lambda runtime in any programming language. A runtime is a program that runs a Lambda function's handler method when the function is invoked. You can include the runtime in your function's deployment package or distribute it in a [layer](#). When you create the Lambda function, choose an [OS-only runtime](#) (the provided runtime family).

Note

Creating a custom runtime is an advanced use case. If you're looking for information about compiling to a native binary or using a third-party off-the-shelf runtime, see [When to use Lambda's OS-only runtimes](#).

For a walkthrough of the custom runtime deployment process, see [Tutorial: Building a custom runtime](#).

Topics

- [Requirements](#)
- [Implementing response streaming in a custom runtime](#)
- [Building custom runtimes for Lambda Managed Instances](#)

Requirements

Custom runtimes must complete certain initialization and processing tasks. A runtime runs the function's setup code, reads the handler name from an environment variable, and reads invocation events from the Lambda runtime API. The runtime passes the event data to the function handler, and posts the response from the handler back to Lambda.

Initialization tasks

The initialization tasks run once [per instance of the function](#) to prepare the environment to handle invocations.

- **Retrieve settings** – Read environment variables to get details about the function and environment.
 - `_HANDLER` – The location to the handler, from the function's configuration. The standard format is *file.method*, where *file* is the name of the file without an extension, and *method* is the name of a method or function that's defined in the file.
 - `LAMBDA_TASK_ROOT` – The directory that contains the function code.
 - `AWS_LAMBDA_RUNTIME_API` – The host and port of the runtime API.

For a full list of available variables, see [Defined runtime environment variables](#).

- **Initialize the function** – Load the handler file and run any global or static code that it contains. Functions should create static resources like SDK clients and database connections once, and reuse them for multiple invocations.
- **Handle errors** – If an error occurs, call the [initialization error](#) API and exit immediately.

Initialization counts towards billed execution time and timeout. When an execution triggers the initialization of a new instance of your function, you can see the initialization time in the logs and [AWS X-Ray trace](#).

Example log

```
REPORT RequestId: f8ac1208... Init Duration: 48.26 ms   Duration: 237.17 ms   Billed
Duration: 300 ms   Memory Size: 128 MB   Max Memory Used: 26 MB
```

Processing tasks

While it runs, a runtime uses the [Lambda runtime interface](#) to manage incoming events and report errors. After completing initialization tasks, the runtime processes incoming events in a loop. In your runtime code, perform the following steps in order.

- **Get an event** – Call the [next invocation](#) API to get the next event. The response body contains the event data. Response headers contain the request ID and other information.

- **Propagate the tracing header** – Get the X-Ray tracing header from the Lambda-Runtime-Trace-Id header in the API response. Set the `_X_AMZN_TRACE_ID` environment variable locally with the same value. The X-Ray SDK uses this value to connect trace data between services.
- **Create a context object** – Create an object with context information from environment variables and headers in the API response.
- **Invoke the function handler** – Pass the event and context object to the handler.
- **Handle the response** – Call the [invocation response](#) API to post the response from the handler.
- **Handle errors** – If an error occurs, call the [invocation error](#) API.
- **Cleanup** – Release unused resources, send data to other services, or perform additional tasks before getting the next event.

Entrypoint

A custom runtime's entry point is an executable file named `bootstrap`. The bootstrap file can be the runtime, or it can invoke another file that creates the runtime. If the root of your deployment package doesn't contain a file named `bootstrap`, Lambda looks for the file in the function's layers. If the `bootstrap` file doesn't exist or isn't executable, your function returns a `Runtime.InvalidEntrypoint` error upon invocation.

Here's an example `bootstrap` file that uses a bundled version of Node.js to run a JavaScript runtime in a separate file named `runtime.js`.

Example bootstrap

```
#!/bin/sh
cd $LAMBDA_TASK_ROOT
./node-v11.1.0-linux-x64/bin/node runtime.js
```

Implementing response streaming in a custom runtime

For [response streaming functions](#), the response and error endpoints have slightly modified behavior that lets the runtime stream partial responses to the client and return payloads in chunks. For more information about the specific behavior, see the following:

- `/runtime/invocation/AwsRequestId/response` – Propagates the `Content-Type` header from the runtime to send to the client. Lambda returns the response payload in chunks via HTTP/1.1 chunked transfer encoding. The response stream can be a maximum size of 20 MiB. To stream the response to Lambda, the runtime must:

- Set the `Lambda-Runtime-Function-Response-Mode` HTTP header to `streaming`.
- Set the `Transfer-Encoding` header to `chunked`.
- Write the response conforming to the HTTP/1.1 chunked transfer encoding specification.
- Close the underlying connection after it has successfully written the response.
- `/runtime/invoke/RequestId/error` – The runtime can use this endpoint to report function or runtime errors to Lambda, which also accepts the `Transfer-Encoding` header. This endpoint can only be called before the runtime begins sending an invocation response.
- Report midstream errors using error trailers in `/runtime/invoke/RequestId/` response – To report errors that occur after the runtime starts writing the invocation response, the runtime can optionally attach HTTP trailing headers named `Lambda-Runtime-Function-Error-Type` and `Lambda-Runtime-Function-Error-Body`. Lambda treats this as a successful response and forwards the error metadata that the runtime provides to the client.

Note

To attach trailing headers, the runtime must set the `Trailer` header value at the beginning of the HTTP request. This is a requirement of the HTTP/1.1 chunked transfer encoding specification.

- `Lambda-Runtime-Function-Error-Type` – The error type that the runtime encountered. This header consists of a string value. Lambda accepts any string, but we recommend a format of `<category.reason>`. For example, `Runtime.APIKeyNotFound`.
- `Lambda-Runtime-Function-Error-Body` – Base64-encoded information about the error.

Building custom runtimes for Lambda Managed Instances

Lambda Managed Instances use the same runtime API as Lambda (default) functions. However, there are key differences in how custom runtimes must be implemented to support the concurrent execution model of Managed Instances.

Concurrent request handling

The primary difference when building custom runtimes for Managed Instances is support for concurrent invocations. Unlike Lambda (default) functions where the runtime processes one

invocation at a time, Managed Instances can process multiple invocations simultaneously within a single execution environment.

Your custom runtime must:

- **Support concurrent /next requests** – The runtime can make multiple simultaneous calls to the [next invocation](#) API, up to the limit specified by the `AWS_LAMBDA_MAX_CONCURRENCY` environment variable.
- **Handle concurrent /response requests** – Multiple invocations can call the [invocation response](#) API simultaneously.
- **Implement thread-safe request handling** – Ensure that concurrent invocations don't interfere with each other by properly managing shared resources and state.
- **Use unique request IDs** – Track each invocation separately using the `Lambda-Runtime-Aws-Request-Id` header to match responses with their corresponding requests.

Implementation pattern

A typical implementation pattern for Managed Instances runtimes involves creating worker threads or processes to handle concurrent invocations:

1. **Read the concurrency limit** – At initialization, read the `AWS_LAMBDA_MAX_CONCURRENCY` environment variable to determine how many concurrent invocations to support.
2. **Create worker pool** – Initialize a pool of workers (threads, processes, or async tasks) equal to the concurrency limit.
3. **Worker processing loop** – Each worker independently:
 - Calls `/runtime/invocation/next` to get an invocation event
 - Invokes the function handler with the event data
 - Posts the response to `/runtime/invocation/AwsRequestId/response`
 - Repeats the loop

Additional considerations

- **Logging format** – Managed Instances only support JSON log format. Ensure your runtime respects the `AWS_LAMBDA_LOG_FORMAT` environment variable and only uses JSON format. For more information, see [Configuring JSON and plain text log formats](#).

- **Shared resources** – Be cautious when using shared resources like the `/tmp` directory with concurrent invocations. Implement proper locking mechanisms to prevent race conditions.

For more information about Lambda Managed Instances execution environments, see [Understanding the Lambda Managed Instances execution environment](#).

Tutorial: Building a custom runtime

In this tutorial, you create a Lambda function with a custom runtime. You start by including the runtime in the function's deployment package. Then you migrate it to a layer that you manage independently from the function. Finally, you share the runtime layer with the world by updating its resource-based permissions policy.

Prerequisites

This tutorial assumes that you have some knowledge of basic Lambda operations and the Lambda console. If you haven't already, follow the instructions in [Create a Lambda function with the console](#) to create your first Lambda function.

To complete the following steps, you need the [AWS CLI version 2](#). Commands and the expected output are listed in separate blocks:

```
aws --version
```

You should see the following output:

```
aws-cli/2.13.27 Python/3.11.6 Linux/4.14.328-248.540.amzn2.x86_64 exe/x86_64.amzn.2
```

For long commands, an escape character (`\`) is used to split a command over multiple lines.

On Linux and macOS, use your preferred shell and package manager.

Note

In Windows, some Bash CLI commands that you commonly use with Lambda (such as `zip`) are not supported by the operating system's built-in terminals. To get a Windows-integrated version of Ubuntu and Bash, [install the Windows Subsystem for Linux](#). Example CLI commands in this guide use Linux formatting. Commands which include inline JSON documents must be reformatted if you are using the Windows CLI.

You need an IAM role to create a Lambda function. The role needs permission to send logs to CloudWatch Logs and access the AWS services that your function uses. If you don't have a role for function development, create one now.

To create an execution role

1. Open the [roles page](#) in the IAM console.
2. Choose **Create role**.
3. Create a role with the following properties.
 - **Trusted entity** – **Lambda**.
 - **Permissions** – **AWSLambdaBasicExecutionRole**.
 - **Role name** – **lambda-role**.

The **AWSLambdaBasicExecutionRole** policy has the permissions that the function needs to write logs to CloudWatch Logs.

Create a function

Create a Lambda function with a custom runtime. This example includes two files: a runtime bootstrap file and a function handler. Both are implemented in Bash.

1. Create a directory for the project, and then switch to that directory.

```
mkdir runtime-tutorial
cd runtime-tutorial
```

2. Create a new file called `bootstrap`. This is the custom runtime.

Example bootstrap

```
#!/bin/sh

set -euo pipefail

# Initialization - load function handler
source $LAMBDA_TASK_ROOT/"$(echo $_HANDLER | cut -d. -f1).sh"

# Processing
```

```

while true
do
    HEADERS="$(mktemp)"
    # Get an event. The HTTP request will block until one is received
    EVENT_DATA=$(curl -sS -LD "$HEADERS" "http://
${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invoke/next")

    # Extract request ID by scraping response headers received above
    REQUEST_ID=$(grep -Fi Lambda-Request-Id "$HEADERS" | tr -d
'[:space:]' | cut -d: -f2)

    # Run the handler function from the script
    RESPONSE=$(echo "$_HANDLER" | cut -d. -f2) "$EVENT_DATA")

    # Send the response
    curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invoke/$REQUEST_ID/
response" -d "$RESPONSE"
done

```

The runtime loads a function script from the deployment package. It uses two variables to locate the script. `LAMBDA_TASK_ROOT` tells it where the package was extracted, and `_HANDLER` includes the name of the script.

After the runtime loads the function script, it uses the runtime API to retrieve an invocation event from Lambda, passes the event to the handler, and posts the response back to Lambda. To get the request ID, the runtime saves the headers from the API response to a temporary file, and reads the `Lambda-Request-Id` header from the file.

Note

Runtimes have additional responsibilities, including error handling, and providing context information to the handler. For details, see [Requirements](#).

3. Create a script for the function. The following example script defines a handler function that takes event data, logs it to `stderr`, and returns it.

Example `function.sh`

```

function handler () {
    EVENT_DATA=$1
    echo "$EVENT_DATA" 1>&2;
}

```

```
RESPONSE="Echoing request: '$EVENT_DATA'"

echo $RESPONSE
}
```

The `runtime-tutorial` directory should now look like this:

```
runtime-tutorial
# bootstrap
# function.sh
```

4. Make the files executable and add them to a `.zip` file archive. This is the deployment package.

```
chmod 755 function.sh bootstrap
zip function.zip function.sh bootstrap
```

5. Create a function named `bash-runtime`. For `--role`, enter the ARN of your Lambda [execution role](#).

```
aws lambda create-function --function-name bash-runtime \
--zip-file fileb://function.zip --handler function.handler --runtime
provided.al2023 \
--role arn:aws:iam::123456789012:role/lambda-role
```

6. Invoke the function.

```
aws lambda invoke --function-name bash-runtime --payload '{"text":"Hello"}'
response.txt --cli-binary-format raw-in-base64-out
```

The **`cli-binary-format`** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see a response like this:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
```

7. Verify the response.

```
cat response.txt
```

You should see a response like this:

```
Echoing request: '{"text":"Hello"}'
```

Create a layer

To separate the runtime code from the function code, create a layer that only contains the runtime. Layers let you develop your function's dependencies independently, and can reduce storage usage when you use the same layer with multiple functions. For more information, see [Managing Lambda dependencies with layers](#).

1. Create a .zip file that contains the bootstrap file.

```
zip runtime.zip bootstrap
```

2. Create a layer with the [publish-layer-version](#) command.

```
aws lambda publish-layer-version --layer-name bash-runtime --zip-file fileb://  
runtime.zip
```

This creates the first version of the layer.

Update the function

To use the runtime layer in the function, configure the function to use the layer, and remove the runtime code from the function.

1. Update the function configuration to pull in the layer.

```
aws lambda update-function-configuration --function-name bash-runtime \  
--layers arn:aws:lambda:us-east-1:123456789012:layer:bash-runtime:1
```

This adds the runtime to the function in the `/opt` directory. To ensure that Lambda uses the runtime in the layer, you must remove the bootstrap from the function's deployment package, as shown in the next two steps.

2. Create a `.zip` file that contains the function code.

```
zip function-only.zip function.sh
```

3. Update the function code to only include the handler script.

```
aws lambda update-function-code --function-name bash-runtime --zip-file fileb://function-only.zip
```

4. Invoke the function to confirm that it works with the runtime layer.

```
aws lambda invoke --function-name bash-runtime --payload '{"text":"Hello"}' response.txt --cli-binary-format raw-in-base64-out
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see a response like this:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
```

5. Verify the response.

```
cat response.txt
```

You should see a response like this:

```
Echoing request: '{"text":"Hello"}'
```

Update the runtime

1. To log information about the execution environment, update the runtime script to output environment variables.

Example bootstrap

```
#!/bin/sh

set -euo pipefail

# Configure runtime to output environment variables
echo "## Environment variables:"
env

# Load function handler
source $LAMBDA_TASK_ROOT/"$(echo $_HANDLER | cut -d. -f1).sh"

# Processing
while true
do
    HEADERS="$(mktemp)"
    # Get an event. The HTTP request will block until one is received
    EVENT_DATA=$(curl -sS -LD "$HEADERS" "http://
${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invoke/next")

    # Extract request ID by scraping response headers received above
    REQUEST_ID=$(grep -Fi Lambda-Request-Id "$HEADERS" | tr -d
'[:space:]' | cut -d: -f2)

    # Run the handler function from the script
    RESPONSE=$(echo "$_HANDLER" | cut -d. -f2) "$EVENT_DATA")

    # Send the response
    curl "http://${AWS_LAMBDA_RUNTIME_API}/2018-06-01/runtime/invoke/$REQUEST_ID/
response" -d "$RESPONSE"
done
```

2. Create a .zip file that contains the new version of the bootstrap file.

```
zip runtime.zip bootstrap
```

3. Create a new version of the bash-runtime layer.

```
aws lambda publish-layer-version --layer-name bash-runtime --zip-file fileb://runtime.zip
```

4. Configure the function to use the new version of the layer.

```
aws lambda update-function-configuration --function-name bash-runtime \
--layers arn:aws:lambda:us-east-1:123456789012:layer:bash-runtime:2
```

Share the layer

To share a layer with another AWS account, add a cross-account permissions statement to the layer's [resource-based policy](#). Run the [add-layer-version-permission](#) command and specify the account ID as the principal. In each statement, you can grant permission to a single account, all accounts, or an organization in [AWS Organizations](#).

The following example grants account 111122223333 access to version 2 of the bash-runtime layer.

```
aws lambda add-layer-version-permission \
  --layer-name bash-runtime \
  --version-number 2 \
  --statement-id xaccount \
  --action lambda:GetLayerVersion \
  --principal 111122223333 \
  --output text
```

You should see output similar to the following:

```
{"Sid":"xaccount","Effect":"Allow","Principal":
{"AWS":"arn:aws:iam::111122223333:root"},"Action":"lambda:GetLayerVersion","Resource":"arn:aws:
east-1:123456789012:layer:bash-runtime:2"}
```

Permissions apply only to a single layer version. Repeat the process each time that you create a new layer version.

Clean up

Delete each version of the layer.

```
aws lambda delete-layer-version --layer-name bash-runtime --version-number 1
aws lambda delete-layer-version --layer-name bash-runtime --version-number 2
```

Because the function holds a reference to version 2 of the layer, it still exists in Lambda. The function continues to work, but functions can no longer be configured to use the deleted version. If you modify the list of layers on the function, you must specify a new version or omit the deleted layer.

Delete the function with the [delete-function](#) command.

```
aws lambda delete-function --function-name bash-runtime
```

Open source repositories

AWS Lambda provides a variety of open source tools, libraries, and components to help you build, customize, and optimize your serverless applications. These resources include runtime interface clients, event libraries, container base images, development tools, and sample projects that are maintained by AWS and available on GitHub. By leveraging these open source repositories, you can extend Lambda's capabilities, create custom runtimes, process events from various AWS services, and gain deeper insights into your function's performance. This page provides an overview of the key open source projects that support Lambda development.

Runtime Interface Clients

Lambda Runtime Interface Clients (RICs) are open source libraries that implement the [Runtime API](#) and manage the interaction between your function code and the Lambda service. These clients handle receiving invocation events, passing context information, and reporting errors.

The runtime interface clients used by Lambda's managed runtimes and container base images are published as open source. When you build custom runtimes or extend existing ones, you can use these open source libraries to simplify your implementation. The following open source GitHub repositories contain the source code for Lambda's RICs:

- [Node.js Runtime Interface Client](#)
- [Python Runtime Interface Client](#)
- [Java Runtime Interface Client](#)

- [Ruby Runtime Interface Client](#)
- [.NET Runtime Interface Client](#)
- [Rust Runtime Interface Client](#)
- [Go Runtime Interface Client](#)
- [Swift Runtime Interface Client](#) (experimental)
- [C++ Runtime Interface Client](#) (experimental)
- [Lambda Base Images](#)

For more information about using these clients to build custom runtimes, see [the section called “Building a custom runtime”](#).

Event libraries

Lambda event libraries provide type definitions and helper utilities for processing events from various AWS services. These libraries help you parse and handle event data in a type-safe manner, making it easier to work with events from services like Amazon S3, Amazon DynamoDB, and Amazon API Gateway.

For compiled languages, AWS provides the following event libraries:

- [Java Event Library](#)
- [.NET Event Libraries](#)
- [Go Event Library](#)
- [Rust Event Library](#)

For interpreted languages like Node.js, Python, and Ruby, events can be parsed directly as JSON objects without requiring a separate library. However, developers using Node.js and Python can leverage [powertools for AWS Lambda](#), which provides built-in schemas for AWS events that offer type hinting, data validation, and functionality similar to what compiled language libraries provide.

- [Powertools for TypeScript](#)
- [Powertools for Python](#)

Container base images

AWS provides open source container base images that you can use as a starting point for building container images for your Lambda functions. These base images include the runtime interface client and other components needed to run your functions in the Lambda execution environment.

For more information about the available base images and how to use them, see the [AWS Lambda Base Images](#) repository and [the section called “Container images”](#).

Development tools

AWS provides additional open source development tools to help you build and optimize your Lambda functions:

Powertools for AWS Lambda

Powertools for AWS Lambda simplifies serverless development with essential utilities to prevent duplicate processing, and batch processing for multi-record handling and Kafka consumer library. These features help you minimize code complexity and operational overhead.

You can also leverage built-in event schema validation, structured logging and tracing, and parameter store integration which are designed to accelerate the creation of production-ready Lambda functions while following AWS well-architected best practices.

GitHub repositories:

- [Python](#)
- [TypeScript](#)
- [Java](#)
- [.NET](#)

Java development tools

- [Java Profiler \(experimental\)](#) - A tool for profiling Java Lambda functions.
- [Java Libraries](#) - A repository that contains a comprehensive collection of Java libraries and tools for Lambda development, including key projects such as JUnit testing utilities and profiling tools.
- [Serverless Java Container](#) - A library that enables you to run existing Java applications on Lambda with minimal changes.

.NET development tools

The [AWS Lambda .NET](#) repository provides .NET libraries and tools for Lambda development, including key projects such as for AWS Lambda tools for the .NET CLI and .NET Core server for hosting .NET Core applications.

Sample projects

Explore a comprehensive collection of sample Lambda projects and applications at [Serverless Land repositories](#). These samples demonstrate various Lambda use cases, integration patterns, and best practices to help you get started with your serverless applications.

Configuring AWS Lambda functions

Learn how to configure the core capabilities and options for your Lambda function using the Lambda API or console.

[.zip file archives](#)

Create a Lambda function deployment package when you want to include dependencies, custom runtime layers, or any files beyond your function code. The deployment package is a .zip file archive containing your function code and dependencies.

[Container images](#)

Use container images to package your function code and dependencies when you need more control over the build process, or if your function requires custom runtime configurations. You can build, test, and deploy Lambda functions as container images using tools like Docker CLI.

[Memory](#)

Learn how and when to increase function memory.

[Ephemeral storage](#)

Learn how and when to increase your function's temporary storage capacity.

[Timeout](#)

Learn how and when to increase your function's timeout value.

[Durable configuration](#)

Enable your Lambda functions to run for extended periods—up to one year—while maintaining state between invocations. Configure execution timeouts, state retention, and versioning behavior for long-running, stateful workflows. Durable functions allow you to build complex, multi-step processes that can pause, resume, and automatically handle interruptions.

[Environment variables](#)

You can make your function code portable and keep secrets out of your code by storing them in your function's configuration by using environment variables.

[Outbound networking](#)

You can use your Lambda function with AWS resources in an Amazon VPC. Connecting your function to a VPC lets you access resources in a private subnet such as relational databases and caches.

[Inbound networking](#)

You can use an interface VPC endpoint to invoke your Lambda functions without crossing the public internet.

[File system](#)

You can use your Lambda function to mount a Amazon EFS to a local directory. A file system allows your function code to access and modify shared resources safely and at high concurrency.

[Aliases](#)

You can configure your clients to invoke a specific Lambda function version by using an alias, instead of updating the client.

[Versions](#)

By publishing a version of your function, you can store your code and configuration as a separate resource that cannot be changed.

[Tags](#)

Use tags to enable attribute-based access control (ABAC), to organize your Lambda functions, and to filter and generate reports on your functions using the AWS Cost Explorer or AWS Billing and Cost Management services.

[Response streaming](#)

You can configure your Lambda function URLs to stream response payloads back to clients. Response streaming can benefit latency sensitive applications by improving time to first byte (TTFB) performance. This is because you can send partial responses back to the client as they become available. Additionally, you can use response streaming to build functions that return larger payloads.

Deploying Lambda functions as .zip file archives

When you create a Lambda function, you package your function code into a deployment package. Lambda supports two types of deployment packages: container images and .zip file archives. The workflow to create a function depends on the deployment package type. To configure a function defined as a container image, see [the section called “Container images”](#).

You can use the Lambda console and the Lambda API to create a function defined with a .zip file archive. You can also upload an updated .zip file to change the function code.

Note

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

Topics

- [Creating the function](#)
- [Using the console code editor](#)
- [Updating function code](#)
- [Changing the runtime](#)
- [Changing the architecture](#)
- [Using the Lambda API](#)
- [Downloading your function code](#)
- [CloudFormation](#)
- [Encrypting Lambda .zip deployment packages](#)

Creating the function

When you create a function defined with a .zip file archive, you choose a code template, the language version, and the execution role for the function. You add your function code after Lambda creates the function.

To create the function

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Choose **Author from scratch** or **Use a blueprint** to create your function.
4. Under **Basic information**, do the following:
 - a. For **Function name**, enter the function name. Function names are limited to 64 characters in length.
 - b. For **Runtime**, choose the language version to use for your function.
 - c. (Optional) For **Architecture**, choose the instruction set architecture to use for your function. The default architecture is x86_64. When you build the deployment package for your function, make sure that it is compatible with this [instruction set architecture](#).
5. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing role.
6. (Optional) Expand **Advanced settings**. You can choose a **Code signing configuration** for the function. You can also configure an (Amazon VPC) for the function to access.
7. Choose **Create function**.

Lambda creates the new function. You can now use the console to add the function code and configure other function parameters and features. For code deployment instructions, see the handler page for the runtime your function uses.

Node.js

Java

[Deploy Java Lambda functions with .zip or JAR file archives](#)

Go

[Deploy Go Lambda functions with .zip file archives](#)

C#

[Build and deploy C# Lambda functions with .zip file archives](#)

PowerShell

[Deploy PowerShell Lambda functions with .zip file archives](#)

Using the console code editor

The console creates a Lambda function with a single source file. For scripting languages, you can edit this file and add more files using the built-in code editor. To save your changes, choose **Save**. Then, to run your code, choose **Test**.

When you save your function code, the Lambda console creates a .zip file archive deployment package. When you develop your function code outside of the console (using an IDE) you need to [create a deployment package](#) to upload your code to the Lambda function.

Updating function code

For scripting languages (Node.js, Python, and Ruby), you can edit your function code in the embedded code editor. If the code is larger than 3MB, or if you need to add libraries, or for languages that the editor doesn't support (Java, Go, C#), you must upload your function code as a .zip archive. If the .zip file archive is smaller than 50 MB, you can upload the .zip file archive from your local machine. If the file is larger than 50 MB, upload the file to the function from an Amazon S3 bucket.

To upload function code as a .zip archive

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function to update and choose the **Code** tab.
3. Under **Code source**, choose **Upload from**.
4. Choose **.zip file**, and then choose **Upload**.
 - In the file chooser, select the new image version, choose **Open**, and then choose **Save**.

5. (Alternative to step 4) Choose **Amazon S3 location**.

- In the text box, enter the S3 link URL of the .zip file archive, then choose **Save**.

Changing the runtime

If you update the function configuration to use a new runtime, you may need to update the function code to be compatible with the new runtime. If you update the function configuration to use a different runtime, you **must** provide new function code that is compatible with the runtime and architecture. For instructions on how to create a deployment package for the function code, see the handler page for the runtime that the function uses.

The Node.js 20, Python 3.12, Java 21, .NET 8, Ruby 3.3, and later base images are based on the Amazon Linux 2023 minimal container image. Earlier base images use Amazon Linux 2. AL2023 provides several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as glibc. For more information, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

To change the runtime

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function to update and choose the **Code** tab.
3. Scroll down to the **Runtime settings** section, which is under the code editor.
4. Choose **Edit**.
 - a. For **Runtime**, select the runtime identifier.
 - b. For **Handler**, specify file name and handler for your function.
 - c. For **Architecture**, choose the instruction set architecture to use for your function.
5. Choose **Save**.

Changing the architecture

Before you can change the instruction set architecture, you need to ensure that your function's code is compatible with the target architecture.

If you use Node.js, Python, or Ruby and you edit your function code in the embedded editor, the existing code may run without modification.

However, if you provide your function code using a .zip file archive deployment package, you must prepare a new .zip file archive that is compiled and built correctly for the target runtime and instruction-set architecture. For instructions, see the handler page for your function runtime.

To change the instruction set architecture

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function to update and choose the **Code** tab.
3. Under **Runtime settings**, choose **Edit**.
4. For **Architecture**, choose the instruction set architecture to use for your function.
5. Choose **Save**.

Using the Lambda API

To create and configure a function that uses a .zip file archive, use the following API operations:

- [CreateFunction](#)
- [UpdateFunctionCode](#)
- [UpdateFunctionConfiguration](#)

Downloading your function code

You can download the current unpublished (\$LATEST) version of your function code .zip via the Lambda console. To do this, first ensure that you have the following IAM permissions:

- iam:GetPolicy
- iam:GetPolicyVersion
- iam:GetRole
- iam:GetRolePolicy
- iam:ListAttachedRolePolicies
- iam:ListRolePolicies
- iam:ListRoles

To download the function code .zip

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function you want to download the function code .zip for.
3. In the **Function overview**, choose the **Download** button, then choose **Download function code .zip**.
 - Alternatively, choose **Download AWS SAM file** to generate and download a SAM template based on your function's configuration. You can also choose **Download both** to download both the .zip and the SAM template.

CloudFormation

You can use CloudFormation to create a Lambda function that uses a .zip file archive. In your CloudFormation template, the `AWS::Lambda::Function` resource specifies the Lambda function. For descriptions of the properties in the `AWS::Lambda::Function` resource, see [AWS::Lambda::Function](#) in the *AWS CloudFormation User Guide*.

In the `AWS::Lambda::Function` resource, set the following properties to create a function defined as a .zip file archive:

- `AWS::Lambda::Function`
 - `PackageType` – Set to `Zip`.
 - `Code` – Enter the Amazon S3 bucket name and .zip file name in the `S3Bucket` and `S3Key` fields. For Node.js or Python, you can provide inline source code of your Lambda function.
 - `Runtime` – Set the runtime value.
 - `Architecture` – Set the architecture value to `arm64` to use the AWS Graviton2 processor. By default, the architecture value is `x86_64`.

Encrypting Lambda .zip deployment packages

Lambda always provides server-side encryption at rest for .zip deployment packages and function configuration details with an AWS KMS key. By default, Lambda uses an [AWS owned key](#). If this default behavior suits your workflow, you don't need to set up anything else. AWS doesn't charge you to use this key.

If you prefer, you can provide an AWS KMS customer managed key instead. You might do this to have control over rotation of the KMS key or to meet the requirements of your organization for managing KMS keys. When you use a customer managed key, only users in your account with access to the KMS key can view or manage the function's code or configuration.

Customer managed keys incur standard AWS KMS charges. For more information, see [AWS Key Management Service pricing](#).

Create a customer managed key

You can create a symmetric customer managed key by using the AWS Management Console, or the AWS KMS APIs.

To create a symmetric customer managed key

Follow the steps for [Creating symmetric encryption Creating symmetric KMS keys](#) in the *AWS Key Management Service Developer Guide*.

Permissions

Key policy

[Key policies](#) control access to your customer managed key. Every customer managed key must have exactly one key policy, which contains statements that determine who can use the key and how they can use it. For more information, see [How to change a key policy](#) in the *AWS Key Management Service Developer Guide*.

When you use a customer managed key to encrypt a .zip deployment package, Lambda doesn't add a [grant](#) to the key. Instead, your AWS KMS key policy must allow Lambda to call the following AWS KMS API operations on your behalf:

- [kms:GenerateDataKey](#)
- [kms:Decrypt](#)

The following example key policy allows all Lambda functions in account 111122223333 to call the required AWS KMS operations for the specified customer managed key:

Example AWS KMS key policy

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Action": [
        "kms:GenerateDataKey",
        "kms:Decrypt"
      ],
      "Resource": "arn:aws:kms:us-east-1:111122223333:key/key-id",
      "Condition": {
        "StringLike": {
          "kms:EncryptionContext:aws:lambda:FunctionArn":
            "arn:aws:lambda:us-east-1:111122223333:function:*"
        }
      }
    }
  ]
}
```

For more information about [troubleshooting key access](#), see the *AWS Key Management Service Developer Guide*.

Principal permissions

When you use a customer managed key to encrypt a .zip deployment package, only [principals](#) with access to that key can access the .zip deployment package. For example, principals who don't have access to the customer managed key can't download the .zip package using the presigned S3 URL that's included in the [GetFunction](#) response. An `AccessDeniedException` is returned in the `Code` section of the response.

Example AWS KMS `AccessDeniedException`

```
{
```

```
"Code": {
  "RepositoryType": "S3",
  "Error": {
    "ErrorCode": "AccessDeniedException",
    "Message": "KMS access is denied. Check your KMS permissions. KMS
Exception: AccessDeniedException KMS Message: User: arn:aws:sts::111122223333:assumed-
role/LambdaTestRole/session is not authorized to perform: kms:Decrypt on resource:
arn:aws:kms:us-east-1:111122223333:key/key-id with an explicit deny in a resource-
based policy"
  },
  "SourceKMSKeyArn": "arn:aws:kms:us-east-1:111122223333:key/key-id"
},
...
```

For more information about permissions for AWS KMS keys, see [Authentication and access control for AWS KMS](#).

Using a customer managed key for your .zip deployment package

Use the following API parameters to configure customer managed keys for .zip deployment packages:

- [SourceKMSKeyArn](#): Encrypts the source .zip deployment package (the file that you upload).
- [KMSKeyArn](#): Encrypts [environment variables](#) and [Lambda SnapStart](#) snapshots.

When `SourceKMSKeyArn` and `KMSKeyArn` are both specified, Lambda uses the `KMSKeyArn` key to encrypt the unzipped version of the package that Lambda uses to invoke the function. When `SourceKMSKeyArn` is specified but `KMSKeyArn` is not, Lambda uses an [AWS managed key](#) to encrypt the unzipped version of the package.

Lambda console

To add customer managed key encryption when you create a function

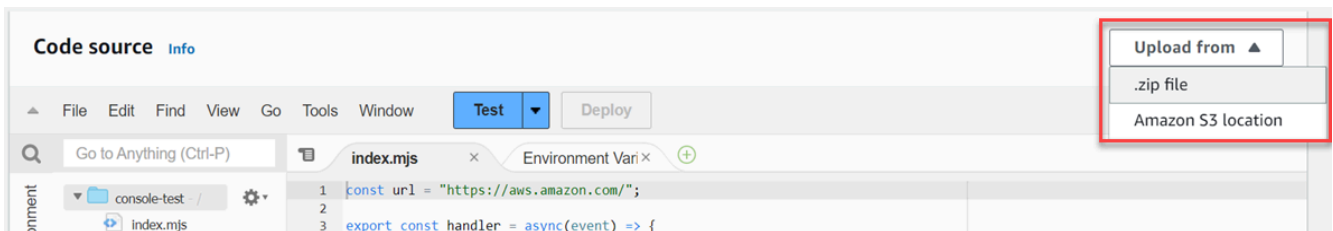

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Choose **Author from scratch** or **Container image**.
4. Under **Basic information**, do the following:
 - a. For **Function name**, enter the function name.

- b. For **Runtime**, choose the language version to use for your function.
5. Expand **Advanced settings**, and then select **Enable encryption with an AWS KMS customer managed key**.
6. Choose a customer managed key.
7. Choose **Create function**.

To remove customer managed key encryption, or to use a different key, you must upload the .zip deployment package again.

To add customer managed key encryption to an existing function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of a function.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip file** or **Amazon S3 location**.

5. Upload the file or enter the Amazon S3 location.
6. Choose **Enable encryption with an AWS KMS customer managed key**.
7. Choose a customer managed key.
8. Choose **Save**.

AWS CLI

To add customer managed key encryption when you create a function

In the following [create-function](#) example:

- `--code`: Specifies the local path to the .zip deployment package (ZipFile) and the customer managed key to encrypt it (SourceKMSKeyArn).
- `--kms-key-arn`: Specifies the customer managed key to encrypt the environment variables and the unzipped version of the deployment package.

```
aws lambda create-function \
  --function-name myFunction \
  --runtime nodejs24.x \
  --handler index.handler \
  --role arn:aws:iam::111122223333:role/service-role/my-lambda-role \
  --code ZipFile=fileb://myFunction.zip,SourceKMSKeyArn=arn:aws:kms:us-east-1:111122223333:key/key-id \
  --kms-key-arn arn:aws:kms:us-east-1:111122223333:key/key2-id
```

In the following [create-function](#) example:

- `--code`: Specifies the location of the .zip file in an Amazon S3 bucket (S3Bucket, S3Key, S3ObjectVersion) and the customer managed key to encrypt it (SourceKMSKeyArn).
- `--kms-key-arn`: Specifies the customer managed key to encrypt the environment variables and the unzipped version of the deployment package.

```
aws lambda create-function \
  --function-name myFunction \
  --runtime nodejs24.x --handler index.handler \
  --role arn:aws:iam::111122223333:role/service-role/my-lambda-role \
  --code S3Bucket=amzn-s3-demo-bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion,SourceKMSKeyArn=arn:aws:kms:us-east-1:111122223333:key/key-id \
  --kms-key-arn arn:aws:kms:us-east-1:111122223333:key/key2-id
```

To add customer managed key encryption to an existing function

In the following [update-function-code](#) example:

- `--zip-file`: Specifies the local path to the .zip deployment package.
- `--source-kms-key-arn`: Specifies the customer managed key to encrypt the zipped version of the deployment package. Lambda uses an AWS owned key to encrypt the unzipped package for function invocations. If you want to use a customer managed key to encrypt the unzipped version of the package, run the [update-function-configuration](#) command with the `--kms-key-arn` option.

```
aws lambda update-function-code \
  --function-name myFunction \
```

```
--zip-file fileb://myFunction.zip \  
--source-kms-key-arn arn:aws:kms:us-east-1:111122223333:key/key-id
```

In the following [update-function-code](#) example:

- `--s3-bucket`: Specifies the location of the .zip file in an Amazon S3 bucket.
- `--s3-key`: Specifies the Amazon S3 key of the deployment package.
- `--s3-object-version`: For versioned objects, the version of the deployment package object to use.
- `--source-kms-key-arn`: Specifies the customer managed key to encrypt the zipped version of the deployment package. Lambda uses an AWS owned key to encrypt the unzipped package for function invocations. If you want to use a customer managed key to encrypt the unzipped version of the package, run the [update-function-configuration](#) command with the `--kms-key-arn` option.

```
aws lambda update-function-code \  
  --function-name myFunction \  
  --s3-bucket amzn-s3-demo-bucket \  
  --s3-key myFileName.zip \  
  --s3-object-version myObject Version \  
  --source-kms-key-arn arn:aws:kms:us-east-1:111122223333:key/key-id
```

To remove customer managed key encryption from an existing function

In the following [update-function-code](#) example, `--zip-file` specifies the local path to the .zip deployment package. When you run this command without the `--source-kms-key-arn` option, Lambda uses an AWS owned key to encrypt the zipped version of the deployment package.

```
aws lambda update-function-code \  
  --function-name myFunction \  
  --zip-file fileb://myFunction.zip
```

Create a Lambda function using a container image

Your AWS Lambda function's code consists of scripts or compiled programs and their dependencies. You use a *deployment package* to deploy your function code to Lambda. Lambda supports two types of deployment packages: container images and .zip file archives.

There are three ways to build a container image for a Lambda function:

- [Using an AWS base image for Lambda](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include a [runtime interface client](#) for your language in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include a [runtime interface client](#) for your language in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

To create a Lambda function from a container image, build your image locally and upload it to an Amazon Elastic Container Registry (Amazon ECR) repository. If you're using a container image provided by an [AWS Marketplace](#) seller, you need to clone the image to your private Amazon ECR

repository first. Then, specify the repository URI when you create the function. The Amazon ECR repository must be in the same AWS Region as the Lambda function. You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

 **Note**

Lambda does not support Amazon ECR FIPS endpoints for container images. If your repository URI includes `ecr-fips`, you are using a FIPS endpoint. Example: `111122223333.dkr.ecr-fips.us-east-1.amazonaws.com`.

This page explains the base image types and requirements for creating Lambda-compatible container images.

 **Note**

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

Topics

- [Requirements](#)
- [Using an AWS base image for Lambda](#)
- [Using an AWS OS-only base image](#)
- [Using a non-AWS base image](#)
- [Runtime interface clients](#)
- [Amazon ECR permissions](#)
- [Function lifecycle](#)

Requirements

Install the [AWS CLI version 2](#) and the [Docker CLI](#). Additionally, note the following requirements:

- The container image must implement the [Using the Lambda runtime API for custom runtimes](#). The AWS open-source [runtime interface clients](#) implement the API. You can add a runtime interface client to your preferred base image to make it compatible with Lambda.
- The container image must be able to run on a read-only file system. Your function code can access a writable `/tmp` directory with between 512 MB and 10,240 MB, in 1-MB increments, of storage.
- The default Lambda user must be able to read all the files required to run your function code. Lambda follows security best practices by defining a default Linux user with least-privileged permissions. This means that you don't need to specify a [USER](#) in your Dockerfile. Verify that your application code does not rely on files that other Linux users are restricted from running.
- Lambda supports only Linux-based container images.
- Lambda provides multi-architecture base images. However, the image you build for your function must target only one of the architectures. Lambda does not support functions that use multi-architecture container images.

Using an AWS base image for Lambda

You can use one of the [AWS base images](#) for Lambda to build the container image for your function code. The base images are preloaded with a language runtime and other components required to run a container image on Lambda. You add your function code and dependencies to the base image and then package it as a container image.

AWS periodically provides updates to the AWS base images for Lambda. If your Dockerfile includes the image name in the `FROM` property, your Docker client pulls the latest version of the image from the [Amazon ECR repository](#). To use the updated base image, you must rebuild your container image and [update the function code](#).

The Node.js 20, Python 3.12, Java 21, .NET 8, Ruby 3.3, and later base images are based on the [Amazon Linux 2023 minimal container image](#). Earlier base images use Amazon Linux 2. AL2023 provides several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as `glibc`.

AL2023-based images use `microdnf` (symlinked as `dnf`) as the package manager instead of `yum`, which is the default package manager in Amazon Linux 2. `microdnf` is a standalone implementation of `dnf`. For a list of packages that are included in AL2023-based images, refer to the **Minimal Container** columns in [Comparing packages installed on Amazon Linux 2023 Container](#)

[Images](#). For more information about the differences between AL2023 and Amazon Linux 2, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

Note

To run AL2023-based images locally, including with AWS Serverless Application Model (AWS SAM), you must use Docker version 20.10.10 or later.

To build a container image using an AWS base image, choose the instructions for your preferred language:

- [Node.js](#)
- [TypeScript](#) (uses a Node.js base image)
- [Python](#)
- [Java](#)
- [Go](#)
- [.NET](#)
- [Ruby](#)

Using an AWS OS-only base image

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include a [runtime interface client](#) for your language in the image.

Amazon Elastic Container Registry Public Gallery: gallery.ecr.aws/lambda/provided

Using a non-AWS base image

Lambda supports any image that conforms to one of the following image manifest formats:

- Docker image manifest V2, schema 2 (used with Docker version 1.10 and newer)
- Open Container Initiative (OCI) Specifications (v1.0.0 and up)

Lambda supports a maximum uncompressed image size of 10 GB, including all layers.

Note

- To make the image compatible with Lambda, you must include a [runtime interface client](#) for your language in the image.
- For optimal performance, keep your image manifest size under 25,400 bytes. To reduce image manifest size, minimize the number of layers in your image and reduce annotations.

Runtime interface clients

If you use an [OS-only base image](#) or an alternative base image, you must include a runtime interface client in your image. The runtime interface client must extend the [Using the Lambda runtime API for custom runtimes](#), which manages the interaction between Lambda and your function code. AWS provides open-source runtime interface clients for the following languages:

- [Node.js](#)
- [Python](#)
- [Java](#)

- [.NET](#)
- [Go](#)
- [Ruby](#)
- [Rust](#) –

If you're using a language that doesn't have an AWS-provided runtime interface client, you must create your own.

Amazon ECR permissions

Before you create a Lambda function from a container image, you must build the image locally and upload it to an Amazon ECR repository. When you create the function, specify the Amazon ECR repository URI.

Make sure that the permissions for the user or role that creates the function includes `GetRepositoryPolicy`, `SetRepositoryPolicy`, `BatchGetImage`, and `GetDownloadUrlForLayer`.

For example, use the IAM console to create a role with the following policy:

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "VisualEditor0",
      "Effect": "Allow",
      "Action": [
        "ecr:SetRepositoryPolicy",
        "ecr:GetRepositoryPolicy",
        "ecr:BatchGetImage",
        "ecr:GetDownloadUrlForLayer"
      ],
      "Resource": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world"
    }
  ]
}
```

Amazon ECR repository policies

For a function in the same account as the container image in Amazon ECR, you can add `ecr:BatchGetImage` and `ecr:GetDownloadUrlForLayer` permissions to your Amazon ECR repository policy. The following example shows the minimum policy:

```
{
  "Sid": "LambdaECRImageRetrievalPolicy",
  "Effect": "Allow",
  "Principal": {
    "Service": "lambda.amazonaws.com"
  },
  "Action": [
    "ecr:BatchGetImage",
    "ecr:GetDownloadUrlForLayer"
  ]
}
```

For more information about Amazon ECR repository permissions, see [Private repository policies](#) in the *Amazon Elastic Container Registry User Guide*.

If the Amazon ECR repository does not include these permissions, Lambda attempts to add them automatically. Lambda can add permissions only if the principal calling Lambda has `ecr:getRepositoryPolicy` and `ecr:setRepositoryPolicy` permissions.

To view or edit your Amazon ECR repository permissions, follow the directions in [Setting a private repository policy statement](#) in the *Amazon Elastic Container Registry User Guide*.

Amazon ECR cross-account permissions

A different account in the same region can create a function that uses a container image owned by your account. In the following example, your [Amazon ECR repository permissions policy](#) needs the following statements to grant access to account number 123456789012.

- **CrossAccountPermission** – Allows account 123456789012 to create and update Lambda functions that use images from this ECR repository.
- **LambdaECRImageCrossAccountRetrievalPolicy** – Lambda will eventually set a function's state to inactive if it is not invoked for an extended period. This statement is required so that Lambda can retrieve the container image for optimization and caching on behalf of the function owned by 123456789012.

Example— Add cross-account permission to your repository

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "CrossAccountPermission",
      "Effect": "Allow",
      "Action": [
        "ecr:BatchGetImage",
        "ecr:GetDownloadUrlForLayer"
      ],
      "Principal": {
        "AWS": "arn:aws:iam::123456789012:root"
      },
      "Resource": "arn:aws:ecr:us-east-1:123456789012:repository/example-lambda-repository"
    },
    {
      "Sid": "LambdaECRIImageCrossAccountRetrievalPolicy",
      "Effect": "Allow",
      "Action": [
        "ecr:BatchGetImage",
        "ecr:GetDownloadUrlForLayer"
      ],
      "Principal": {
        "Service": "lambda.amazonaws.com"
      },
      "Condition": {
        "ArnLike": {
          "aws:sourceARN": "arn:aws:lambda:us-east-1:123456789012:function:*"
        }
      },
      "Resource": "arn:aws:ecr:us-east-1:123456789012:repository/example-lambda-repository"
    }
  ]
}
```

To give access to multiple accounts, you add the account IDs to the Principal list in the `CrossAccountPermission` policy and to the Condition evaluation list in the `LambdaECRIImageCrossAccountRetrievalPolicy`.

If you are working with multiple accounts in an AWS Organization, we recommend that you enumerate each account ID in the ECR permissions policy. This approach aligns with the AWS security best practice of setting narrow permissions in IAM policies.

In addition to Lambda permissions, the user or role that creates the function must also have `BatchGetImage` and `GetDownloadUrlForLayer` permissions.

Function lifecycle

After you upload a new or updated container image, Lambda optimizes the image before the function can process invocations. The optimization process can take a few seconds. The function remains in the `Pending` state until the process completes, when the state transitions to `Active`. You can't invoke the function until it reaches the `Active` state.

If a function is not invoked for multiple weeks, Lambda reclaims its optimized version, and the function transitions to the `Inactive` state. To reactivate the function, you must invoke it. Lambda rejects the first invocation and the function enters the `Pending` state until Lambda re-optimizes the image. The function then returns to the `Active` state.

Lambda periodically fetches the associated container image from the Amazon ECR repository. If the corresponding container image no longer exists on Amazon ECR or permissions are revoked, the function enters the `Failed` state, and Lambda returns a failure for any function invocations.

You can use the Lambda API to get information about a function's state. For more information, see [Lambda function states](#).

Configure Lambda function memory

Lambda allocates CPU power in proportion to the amount of memory configured. *Memory* is the amount of memory available to your Lambda function at runtime. You can increase or decrease the memory and CPU power allocated to your function using the **Memory** setting. You can configure memory between 128 MB and 10,240 MB in 1-MB increments. At 1,769 MB, a function has the equivalent of one vCPU (one vCPU-second of credits per second).

This page describes how and when to update the memory setting for a Lambda function.

Sections

- [Determining the appropriate memory setting for a Lambda function](#)
- [Configuring function memory \(console\)](#)
- [Configuring function memory \(AWS CLI\)](#)
- [Configuring function memory \(AWS SAM\)](#)
- [Accepting function memory recommendations \(console\)](#)

Determining the appropriate memory setting for a Lambda function

Memory is the principal lever for controlling the performance of a function. The default setting, 128 MB, is the lowest possible setting. We recommend that you only use 128 MB for simple Lambda functions, such as those that transform and route events to other AWS services. A higher memory allocation can improve performance for functions that use imported libraries, [Lambda layers](#), Amazon Simple Storage Service (Amazon S3) or Amazon Elastic File System (Amazon EFS). Adding more memory proportionally increases the amount of CPU, increasing the overall computational power available. If a function is CPU, network or memory-bound, then increasing the memory setting can dramatically improve its performance.

To find the right memory configuration, monitor your functions with Amazon CloudWatch and set alarms if memory consumption is approaching the configured maximums. This can help identify memory-bound functions. For CPU-bound and IO-bound functions, monitoring the duration can also provide insight. In these cases, increasing the memory can help resolve the compute or network bottlenecks.

You can also consider using the open source [AWS Lambda Power Tuning](#) tool. This tool uses AWS Step Functions to run multiple concurrent versions of a Lambda function at different

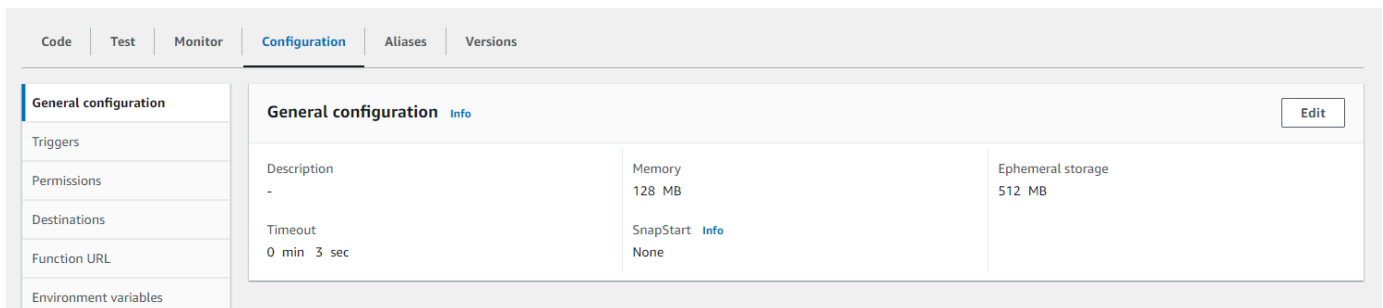

memory allocations and measure the performance. The input function runs in your AWS account, performing live HTTP calls and SDK interaction, to measure likely performance in a live production scenario. You can also implement a CI/CD process to use this tool to automatically measure the performance of new functions that you deploy.

Configuring function memory (console)

You can configure the memory of your function in the Lambda console.

To update the memory of a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab and then choose **General configuration**.

4. Under **General configuration**, choose **Edit**.
5. For **Memory**, set a value from 128 MB to 10,240 MB.
6. Choose **Save**.

Configuring function memory (AWS CLI)

You can use the [update-function-configuration](#) command to configure the memory of your function.

Example

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --memory-size 1024
```

Configuring function memory (AWS SAM)

You can use the [AWS Serverless Application Model](#) to configure memory for your function. Update the [MemorySize](#) property in your `template.yaml` file and then run [sam deploy](#).

Example template.yaml

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: An AWS Serverless Application Model template describing your function.
Resources:
  my-function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: .
      Description: ''
      MemorySize: 1024
      # Other function properties...
```

Accepting function memory recommendations (console)

If you have administrator permissions in AWS Identity and Access Management (IAM), you can opt in to receive Lambda function memory setting recommendations from AWS Compute Optimizer. For instructions on opting in to memory recommendations for your account or organization, see [Opting in your account](#) in the *AWS Compute Optimizer User Guide*.

Note

Compute Optimizer supports only functions that use x86_64 architecture.

When you've opted in and your [Lambda function meets Compute Optimizer requirements](#), you can view and accept function memory recommendations from Compute Optimizer in the Lambda console in **General configuration**.

Configure ephemeral storage for Lambda functions

Lambda provides ephemeral storage for functions in the `/tmp` directory. This storage is temporary and unique to each execution environment. You can control the amount of ephemeral storage allocated to your function using the **Ephemeral storage** setting. You can configure ephemeral storage between 512 MB and 10,240 MB, in 1-MB increments. All data stored in `/tmp` is encrypted at rest with a key managed by AWS.

This page describes common use cases and how to update the ephemeral storage for a Lambda function.

Sections

- [Common use cases for increased ephemeral storage](#)
- [Configuring ephemeral storage \(console\)](#)
- [Configuring ephemeral storage \(AWS CLI\)](#)
- [Configuring ephemeral storage \(AWS SAM\)](#)

Common use cases for increased ephemeral storage

Here are several common use cases that benefit from increased ephemeral storage:

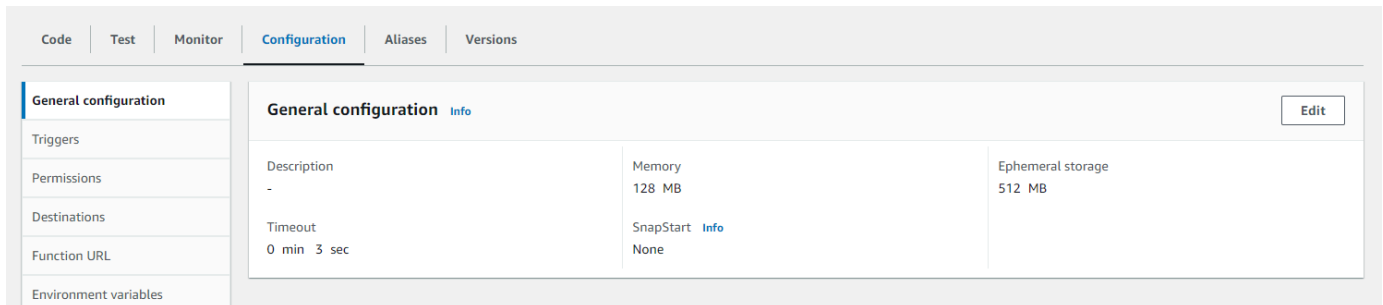

- **Extract-transform-load (ETL) jobs:** Increase ephemeral storage when your code performs intermediate computation or downloads other resources to complete processing. More temporary space enables more complex ETL jobs to run in Lambda functions.
- **Machine learning (ML) inference:** Many inference tasks rely on large reference data files, including libraries and models. With more ephemeral storage, you can download larger models from Amazon Simple Storage Service (Amazon S3) to `/tmp` and use them in your processing.
- **Data processing:** For workloads that download objects from Amazon S3 in response to S3 events, more `/tmp` space makes it possible to handle larger objects without using in-memory processing. Workloads that create PDFs or process media also benefit from more ephemeral storage.
- **Graphics processing:** Image processing is a common use case for Lambda-based applications. For workloads that process large TIFF files or satellite images, more ephemeral storage makes it easier to use libraries and perform the computation in Lambda.

Configuring ephemeral storage (console)

You can configure ephemeral storage in the Lambda console.

To modify ephemeral storage for a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab and then choose **General configuration**.

4. Under **General configuration**, choose **Edit**.
5. For **Ephemeral storage**, set a value between 512 MB and 10,240 MB, in 1-MB increments.
6. Choose **Save**.

Configuring ephemeral storage (AWS CLI)

You can use the [update-function-configuration](#) command to configure ephemeral storage.

Example

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --ephemeral-storage '{"Size": 1024}'
```

Configuring ephemeral storage (AWS SAM)

You can use the [AWS Serverless Application Model](#) to configure ephemeral storage for your function. Update the [EphemeralStorage](#) property in your template .yaml file and then run [sam deploy](#).

Example template.yaml

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: An AWS Serverless Application Model template describing your function.
Resources:
  my-function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: .
      Description: ''
      MemorySize: 128
      Timeout: 120
      Handler: index.handler
      Runtime: nodejs22.x
      Architectures:
        - x86_64
      EphemeralStorage:
        Size: 10240
      # Other function properties...
```

Selecting and configuring an instruction set architecture for your Lambda function

The *instruction set architecture* of a Lambda function determines the type of computer processor that Lambda uses to run the function. Lambda provides a choice of instruction set architectures:

- arm64 – 64-bit ARM architecture, for the AWS Graviton2 processor.
- x86_64 – 64-bit x86 architecture, for x86-based processors.

Note

The arm64 architecture is available in most AWS Regions. For more information, see [AWS Lambda Pricing](#). In the memory prices table, choose the **Arm Price** tab, and then open the **Region** dropdown list to see which AWS Regions support arm64 with Lambda. For an example of how to create a function with arm64 architecture, see [AWS Lambda Functions Powered by AWS Graviton2 Processor](#).

Topics

- [Advantages of using arm64 architecture](#)
- [Requirements for migration to arm64 architecture](#)
- [Function code compatibility with arm64 architecture](#)
- [How to migrate to arm64 architecture](#)
- [Configuring the instruction set architecture](#)

Advantages of using arm64 architecture

Lambda functions that use arm64 architecture (AWS Graviton2 processor) can achieve significantly better price and performance than the equivalent function running on x86_64 architecture. Consider using arm64 for compute-intensive applications such as high-performance computing, video encoding, and simulation workloads.

The Graviton2 CPU uses the Neoverse N1 core and supports Armv8.2 (including CRC and crypto extensions) plus several other architectural extensions.

Graviton2 reduces memory read time by providing a larger L2 cache per vCPU, which improves the latency performance of web and mobile backends, microservices, and data processing systems. Graviton2 also provides improved encryption performance and supports instruction sets that improve the latency of CPU-based machine learning inference.

For more information about AWS Graviton2, see [AWS Graviton Processor](#).

Requirements for migration to arm64 architecture

When you select a Lambda function to migrate to arm64 architecture, to ensure a smooth migration, make sure that your function meets the following requirements:

- The deployment package contains only open-source components and source code that you control, so that you can make any necessary updates for the migration.
- If the function code includes third-party dependencies, each library or package provides an arm64 version.

Function code compatibility with arm64 architecture

Your Lambda function code must be compatible with the instruction set architecture of the function. Before you migrate a function to arm64 architecture, note the following points about the current function code:

- If you added your function code using the embedded code editor, your code probably runs on either architecture without modification.
- If you uploaded your function code, you must upload new code that is compatible with your target architecture.
- If your function uses layers, you must [check each layer](#) to ensure that it is compatible with the new architecture. If a layer is not compatible, edit the function to replace the current layer version with a compatible layer version.
- If your function uses Lambda extensions, you must check each extension to ensure that it is compatible with the new architecture.
- If your function uses a container image deployment package type, you must create a new container image that is compatible with the architecture of the function.

How to migrate to arm64 architecture

To migrate a Lambda function to the arm64 architecture, we recommend following these steps:

1. Build the list of dependencies for your application or workload. Common dependencies include:
 - All the libraries and packages that the function uses.
 - The tools that you use to build, deploy, and test the function, such as compilers, test suites, continuous integration and continuous delivery (CI/CD) pipelines, provisioning tools, and scripts.
 - The Lambda extensions and third-party tools that you use to monitor the function in production.
2. For each of the dependencies, check the version, and then check whether arm64 versions are available.
3. Build an environment to migrate your application.
4. Bootstrap the application.
5. Test and debug the application.
6. Test the performance of the arm64 function. Compare the performance with the x86_64 version.
7. Update your infrastructure pipeline to support arm64 Lambda functions.
8. Stage your deployment to production.

For example, use [alias routing configuration](#) to split traffic between the x86 and arm64 versions of the function, and compare the performance and latency.

For more information about how to create a code environment for arm64 architecture, including language-specific information for Java, Go, .NET, and Python, see the [Getting started with AWS Graviton](#) GitHub repository.

Configuring the instruction set architecture

You can configure the instruction set architecture for new and existing Lambda functions using the Lambda console, AWS SDKs, AWS Command Line Interface (AWS CLI), or CloudFormation. Follow these steps to change the instruction set architecture for an existing Lambda function from the console.

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to configure the instruction set architecture for.

3. On the main **Code** tab, for the **Runtime settings** section, choose **Edit**.
4. Under **Architecture**, choose the instruction set architecture you want your function to use.
5. Choose **Save**.

Configure Lambda function timeout

Lambda runs your code for a set amount of time before timing out. *Timeout* is the maximum amount of time in seconds that a Lambda function can run. The default value for this setting is 3 seconds, but you can adjust this in increments of 1 second up to a maximum value of 900 seconds (15 minutes).

This page describes how and when to update the timeout setting for a Lambda function.

Sections

- [Determining the appropriate timeout value for a Lambda function](#)
- [Configuring timeout \(console\)](#)
- [Configuring timeout \(AWS CLI\)](#)
- [Configuring timeout \(AWS SAM\)](#)

Determining the appropriate timeout value for a Lambda function

If the timeout value is close to the average duration of a function, there is a higher risk that the function will time out unexpectedly. The duration of a function can vary based on the amount of data transfer and processing, and the latency of any services the function interacts with. Some common causes of timeout include:

- Downloads from Amazon Simple Storage Service (Amazon S3) are larger or take longer than average.
- A function makes a request to another service, which takes longer to respond.
- The parameters provided to a function require more computational complexity in the function, which causes the invocation to take longer.

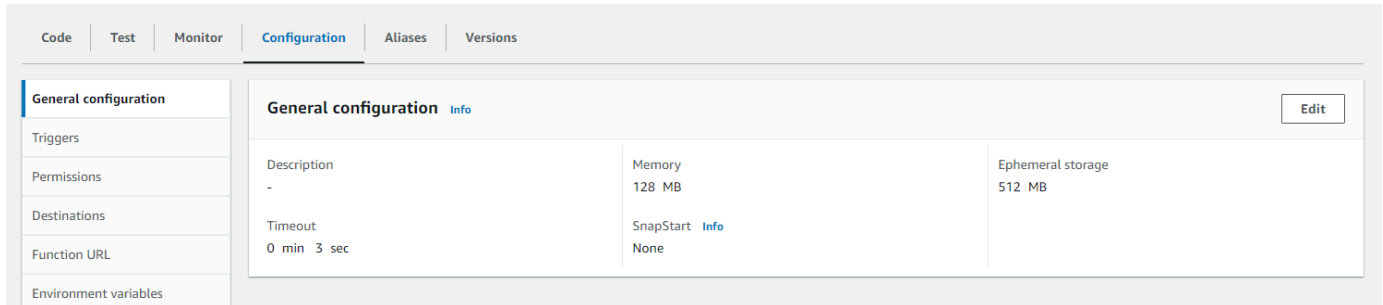

When testing your application, ensure that your tests accurately reflect the size and quantity of data and realistic parameter values. Tests often use small samples for convenience, but you should use datasets at the upper bounds of what is reasonably expected for your workload.

Configuring timeout (console)

You can configure function timeout in the Lambda console.

To modify the timeout for a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab and then choose **General configuration**.

4. Under **General configuration**, choose **Edit**.
5. For **Timeout**, set a value between 1 and 900 seconds (15 minutes).
6. Choose **Save**.

Configuring timeout (AWS CLI)

You can use the [update-function-configuration](#) command to configure the timeout value, in seconds. The following example command increases the function timeout to 120 seconds (2 minutes).

Example

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --timeout 120
```

Configuring timeout (AWS SAM)

You can use the [AWS Serverless Application Model](#) to configure the timeout value for your function. Update the [Timeout](#) property in your `template.yaml` file and then run [sam deploy](#).

Example template.yaml

```
AWSTemplateFormatVersion: '2010-09-09'  
Transform: AWS::Serverless-2016-10-31
```

Description: An AWS Serverless Application Model template describing your function.

Resources:

my-function:

Type: AWS::Serverless::Function

Properties:

CodeUri: .

Description: ''

MemorySize: 128

Timeout: *120*

Other function properties...

Configure Lambda durable functions

To enable durable execution for your Lambda function, you need to configure specific settings that control how long your function can run, how long state data is retained, and what permissions are required.

Enable durable execution

To enable durable execution for your Lambda function, configure the `DurableConfig` in your function configuration. This setting controls execution timeout, state retention, and versioning behavior.

AWS CLI

```
aws lambda update-function-configuration \  
  --function-name my-durable-function \  
  --durable-config '{  
    "ExecutionTimeout": 3600,  
    "RetentionPeriodInDays": 30,  
    "AllowInvokeLatest": true  
  }'
```

CloudFormation

```
Resources:  
  MyDurableFunction:
```

```
Type: AWS::Lambda::Function
Properties:
  FunctionName: my-durable-function
  Runtime: nodejs18.x
  Handler: index.handler
  Code:
    ZipFile: |
      // Your durable function code
  DurableConfig:
    ExecutionTimeout: 3600
    RetentionPeriodInDays: 30
    AllowInvokeLatest: true
```

Configuration parameters:

- `ExecutionTimeout` - Maximum execution time in seconds (up to 31,536,000 for one year)
- `RetentionPeriodInDays` - How long to retain execution state and history (1-365 days)
- `AllowInvokeLatest` - Whether to allow invoking the \$LATEST version for durable execution

IAM permissions for durable functions

Durable functions require additional IAM permissions beyond standard Lambda execution roles. Your function's execution role must include permissions for state management and durable execution APIs.

Minimum required permissions:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "lambda:InvokeFunction",
        "lambda:GetFunction",
        "lambda:ManageDurableState",
        "lambda:GetDurableExecution",
        "lambda:ListDurableExecutions"
      ]
    }
  ]
}
```

```

    ],
    "Resource": "arn:aws:lambda:*:*:function:*"
  },
  {
    "Effect": "Allow",
    "Action": [
      "logs:CreateLogGroup",
      "logs:CreateLogStream",
      "logs:PutLogEvents"
    ],
    "Resource": "arn:aws:logs:*:*:*"
  }
]
}

```

CloudFormation execution role example:

```

DurableFunctionRole:
  Type: AWS::IAM::Role
  Properties:
    AssumeRolePolicyDocument:
      Version: '2012-10-17'
      Statement:
        - Effect: Allow
          Principal:
            Service: lambda.amazonaws.com
          Action: sts:AssumeRole
    ManagedPolicyArns:
      - arn:aws:iam::aws:policy/service-role/AWSLambdaBasicExecutionRole
    Policies:
      - PolicyName: DurableFunctionPolicy
        PolicyDocument:
          Version: '2012-10-17'
          Statement:
            - Effect: Allow
              Action:
                - lambda:ManageDurableState
                - lambda:GetDurableExecution
                - lambda:ListDurableExecutions
              Resource: '*'

```

Configuration best practices

Follow these best practices when configuring durable functions for production use:

- **Set appropriate execution timeouts** - Configure `ExecutionTimeout` based on your workflow's maximum expected duration. Don't set unnecessarily long timeouts as they affect cost and resource allocation.
- **Balance retention with storage costs** - Set `RetentionPeriodInDays` based on your debugging and audit requirements. Longer retention periods increase storage costs.
- **Use versioning in production** - Set `AllowInvokeLatest` to `false` in production environments and use specific function versions or aliases for durable executions.
- **Monitor state size** - Large state objects increase storage costs and can impact performance. Keep state minimal and use external storage for large data.
- **Configure appropriate logging** - Enable detailed logging for troubleshooting long-running workflows, but be mindful of log volume and costs.

Production configuration example:

```
{
  "ExecutionTimeout": 86400,
  "RetentionPeriodInDays": 7,
  "AllowInvokeLatest": false
}
```

Working with Lambda environment variables

You can use environment variables to adjust your function's behavior without updating code. An environment variable is a pair of strings that is stored in a function's version-specific configuration. The Lambda runtime makes environment variables available to your code and sets additional environment variables that contain information about the function and invocation request.

Note

To increase security, we recommend that you use AWS Secrets Manager instead of environment variables to store database credentials and other sensitive information like API keys or authorization tokens. For more information, see [Use Secrets Manager secrets in Lambda functions](#).

Environment variables are not evaluated before the function invocation. Any value you define is considered a literal string and not expanded. Perform the variable evaluation in your function code.

Creating Lambda environment variables

You can configure environment variables in Lambda using the Lambda console, the AWS Command Line Interface (AWS CLI), AWS Serverless Application Model (AWS SAM), or using an AWS SDK.

Console

You define environment variables on the unpublished version of your function. When you publish a version, the environment variables are locked for that version along with other [version-specific configuration settings](#).

You create an environment variable for your function by defining a key and a value. Your function uses the name of the key to retrieve the value of the environment variable.

To set environment variables in the Lambda console

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab, then choose **Environment variables**.
4. Under **Environment variables**, choose **Edit**.
5. Choose **Add environment variable**.

6. Enter a key and value.

Requirements

- Keys start with a letter and are at least two characters.
- Keys only contain letters, numbers, and the underscore character (_).
- Keys aren't [reserved by Lambda](#).
- The total size of all environment variables doesn't exceed 4 KB.

7. Choose **Save**.

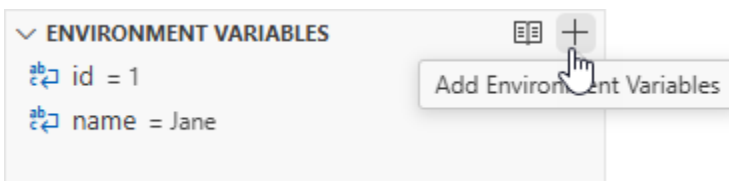

To generate a list of environment variables in the console code editor

You can generate a list of environment variables in the Lambda code editor. This is a quick way to reference your environment variables while you code.

1. Choose the **Code** tab.
2. Scroll down to the **ENVIRONMENT VARIABLES** section of the code editor. Existing environment variables are listed here:

3. To create new environment variables, choose the plus sign

Environment variables remain encrypted when listed in the console code editor. If you enabled encryption helpers for encryption in transit, then those settings remain unchanged. For more information, see [Securing Lambda environment variables](#).

The environment variables list is read-only and is available only on the Lambda console. This file is not included when you download the function's .zip file archive, and you can't add environment variables by uploading this file.

AWS CLI

The following example sets two environment variables on a function named `my-function`.

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --environment "Variables={BUCKET=amzn-s3-demo-bucket,KEY=file.txt}"
```

When you apply environment variables with the `update-function-configuration` command, the entire contents of the `Variables` structure is replaced. To retain existing environment variables when you add a new one, include all existing values in your request.

To get the current configuration, use the `get-function-configuration` command.

```
aws lambda get-function-configuration \  
  --function-name my-function
```

You should see the following output:

```
{  
  "FunctionName": "my-function",  
  "FunctionArn": "arn:aws:lambda:us-east-2:111122223333:function:my-function",  
  "Runtime": "nodejs24.x",  
  "Role": "arn:aws:iam::111122223333:role/lambda-role",  
  "Environment": {  
    "Variables": {  
      "BUCKET": "amzn-s3-demo-bucket",  
      "KEY": "file.txt"  
    }  
  },  
  "RevisionId": "0894d3c1-2a3d-4d48-bf7f-abade99f3c15",  
  ...  
}
```

You can pass the revision ID from the output of `get-function-configuration` as a parameter to `update-function-configuration`. This ensures that the values don't change between when you read the configuration and when you update it.

To configure a function's encryption key, set the `KMSKeyARN` option.

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --environment "Variables={BUCKET=amzn-s3-demo-bucket,KEY=file.txt}"
```

```
--function-name my-function \  
--kms-key-arn arn:aws:kms:us-east-2:111122223333:key/055efbb4-xmpl-4336-  
ba9c-538c7d31f599
```

AWS SAM

You can use the [AWS Serverless Application Model](#) to configure environment variables for your function. Update the [Environment](#) and [Variables](#) properties in your `template.yaml` file and then run [sam deploy](#).

Example `template.yaml`

```
AWSTemplateFormatVersion: '2010-09-09'  
Transform: AWS::Serverless-2016-10-31  
Description: An AWS Serverless Application Model template describing your function.  
Resources:  
  my-function:  
    Type: AWS::Serverless::Function  
    Properties:  
      CodeUri: .  
      Description: ''  
      MemorySize: 128  
      Timeout: 120  
      Handler: index.handler  
      Runtime: nodejs24.x  
      Architectures:  
        - x86_64  
      EphemeralStorage:  
        Size: 10240  
      Environment:  
        Variables:  
          BUCKET: amzn-s3-demo-bucket  
          KEY: file.txt  
      # Other function properties...
```

AWS SDKs

To manage environment variables using an AWS SDK, use the following API operations.

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

To learn more, refer to the [AWS SDK documentation](#) for your preferred programming language.

Example scenario for environment variables

You can use environment variables to customize function behavior in your test environment and production environment. For example, you can create two functions with the same code but different configurations. One function connects to a test database, and the other connects to a production database. In this situation, you use environment variables to pass the hostname and other connection details for the database to the function.

The following example shows how to define the database host and database name as environment variables.

ENVIRONMENT	DEVELOPMENT	Remove
databaseHost	lambdadb	Remove
databaseName	rd1owwlydynnm5.cuovuyfg087	Remove
Key	Value	Remove

If you want your test environment to generate more debug information than the production environment, you could set an environment variable to configure your test environment to use more verbose logging or more detailed tracing.

For example, in your test environment, you could set an environment variable with the key `LOG_LEVEL` and a value indicating a log level of debug or trace. In your Lambda function's code, you can then use this environment variable to set the log level.

The following code examples in Python and Node.js illustrate how you can achieve this. These examples assume your environment variable has a value of `DEBUG` in Python or `debug` in Node.js.

Python

Example Python code to set log level

```
import os
import logging
```

```
# Initialize the logger
logger = logging.getLogger()

# Get the log level from the environment variable and default to INFO if not set
log_level = os.environ.get('LOG_LEVEL', 'INFO')

# Set the log level
logger.setLevel(log_level)

def lambda_handler(event, context):
    # Produce some example log outputs
    logger.debug('This is a log with detailed debug information - shown only in test environment')
    logger.info('This is a log with standard information - shown in production and test environments')
```

Node.js (ES module format)

Example Node.js code to set log level

This example uses the winston logging library. Use npm to add this library to your function's deployment package. For more information, see [the section called “Creating a .zip deployment package with dependencies”](#).

```
import winston from 'winston';

// Initialize the logger using the log level from environment variables, defaulting
// to INFO if not set
const logger = winston.createLogger({
  level: process.env.LOG_LEVEL || 'info',
  format: winston.format.json(),
  transports: [new winston.transports.Console()]
});

export const handler = async (event) => {
  // Produce some example log outputs
  logger.debug('This is a log with detailed debug information - shown only in test environment');
  logger.info('This is a log with standard information - shown in production and test environment');
};
```

Retrieving Lambda environment variables

To retrieve environment variables in your function code, use the standard method for your programming language.

Node.js

```
let region = process.env.AWS_REGION
```

Python

```
import os
region = os.environ['AWS_REGION']
```

Note

In some cases, you may need to use the following format:

```
region = os.environ.get('AWS_REGION')
```

Ruby

```
region = ENV["AWS_REGION"]
```

Java

```
String region = System.getenv("AWS_REGION");
```

Go

```
var region = os.Getenv("AWS_REGION")
```

C#

```
string region = Environment.GetEnvironmentVariable("AWS_REGION");
```

PowerShell

```
$region = $env:AWS_REGION
```

Lambda stores environment variables securely by encrypting them at rest. You can [configure Lambda to use a different encryption key](#), encrypt environment variable values on the client side, or set environment variables in an CloudFormation template with AWS Secrets Manager.

Defined runtime environment variables

Lambda [runtimes](#) set several environment variables during initialization. Most of the environment variables provide information about the function or runtime. The keys for these environment variables are *reserved* and cannot be set in your function configuration.

Reserved environment variables

- `_HANDLER` – The handler location configured on the function.
- `_X_AMZN_TRACE_ID` – The [X-Ray tracing header](#). This environment variable changes with each invocation.
 - This environment variable is not defined for OS-only runtimes (the provided runtime family). You can set `_X_AMZN_TRACE_ID` for custom runtimes using the `Lambda-Runtime-Trace-Id` response header from the [Next invocation](#).
 - For Java runtime versions 17 and later, this environment variable is not used. Instead, Lambda stores tracing information in the `com.amazonaws.xray.traceHeader` system property.
- `AWS_DEFAULT_REGION` – The default AWS Region where the Lambda function is executed.
- `AWS_REGION` – The AWS Region where the Lambda function is executed. If defined, this value overrides the `AWS_DEFAULT_REGION`.
 - For more information about using the AWS Region environment variables with AWS SDKs, see [AWS Region](#) in the *AWS SDKs and Tools Reference Guide*.
- `AWS_EXECUTION_ENV` – The [runtime identifier](#), prefixed by `AWS_Lambda_` (for example, `AWS_Lambda_java8`). This environment variable is not defined for OS-only runtimes (the provided runtime family).
- `AWS_LAMBDA_FUNCTION_NAME` – The name of the function.
- `AWS_LAMBDA_FUNCTION_MEMORY_SIZE` – The amount of memory available to the function in MB.

- `AWS_LAMBDA_FUNCTION_VERSION` – The version of the function being executed.
- `AWS_LAMBDA_INITIALIZATION_TYPE` – The initialization type of the function, which is on-demand, provisioned-concurrency, snap-start, or lambda-managed-instances. For information, see [Configuring provisioned concurrency](#), [Improving startup performance with Lambda SnapStart](#), or [Lambda Managed Instances](#).
- `AWS_LAMBDA_LOG_GROUP_NAME`, `AWS_LAMBDA_LOG_STREAM_NAME` – The name of the Amazon CloudWatch Logs group and stream for the function. The `AWS_LAMBDA_LOG_GROUP_NAME` and `AWS_LAMBDA_LOG_STREAM_NAME` [environment variables](#) are not available in Lambda SnapStart functions.
- `AWS_ACCESS_KEY`, `AWS_ACCESS_KEY_ID`, `AWS_SECRET_ACCESS_KEY`, `AWS_SESSION_TOKEN` – The access keys obtained from the function's [execution role](#).
- `AWS_LAMBDA_RUNTIME_API` – ([Custom runtime](#)) The host and port of the [runtime API](#).
- `LAMBDA_TASK_ROOT` – The path to your Lambda function code.
- `LAMBDA_RUNTIME_DIR` – The path to runtime libraries.
- `AWS_LAMBDA_MAX_CONCURRENCY` – (Lambda Managed Instances only) The maximum number of concurrent invocations Lambda will send to one execution environment.

The following additional environment variables aren't reserved and can be extended in your function configuration.

Unreserved environment variables

- `LANG` – The locale of the runtime (`en_US.UTF-8`).
- `PATH` – The execution path (`/usr/local/bin:/usr/bin:/bin:/opt/bin`).
- `LD_LIBRARY_PATH` – The system library path (`/var/lang/lib:/lib64:/usr/lib64:$LAMBDA_RUNTIME_DIR:$LAMBDA_RUNTIME_DIR/lib:$LAMBDA_TASK_ROOT:$LAMBDA_TASK_ROOT/lib:/opt/lib`).
- `NODE_PATH` – ([Node.js](#)) The Node.js library path (`/opt/nodejs/node12/node_modules:/opt/nodejs/node_modules:$LAMBDA_RUNTIME_DIR/node_modules`).
- `NODE_OPTIONS` – ([Node.js](#)) For Node.js runtimes, you can use `NODE_OPTIONS` to re-enable experimental features that Lambda disables by default.
- `PYTHONPATH` – ([Python](#)) The Python library path (`$LAMBDA_RUNTIME_DIR`).
- `GEM_PATH` – ([Ruby](#)) The Ruby library path (`$LAMBDA_TASK_ROOT/vendor/bundle/ruby/3.3.0:/opt/ruby/gems/3.3.0`).

- `AWS_XRAY_CONTEXT_MISSING` – For X-Ray tracing, Lambda sets this to `LOG_ERROR` to avoid throwing runtime errors from the X-Ray SDK.
- `AWS_XRAY_DAEMON_ADDRESS` – For X-Ray tracing, the IP address and port of the X-Ray daemon.
- `AWS_LAMBDA_DOTNET_PREJIT` – ([.NET](#)) Set this variable to enable or disable .NET specific runtime optimizations. Values include `always`, `never`, and `provisioned-concurrency`. For more information, see [Configuring provisioned concurrency for a function](#).
- `TZ` – The environment's time zone (:UTC). The execution environment uses NTP to synchronize the system clock.

The sample values shown reflect the latest runtimes. The presence of specific variables or their values can vary on earlier runtimes.

Securing Lambda environment variables

For securing your environment variables, you can use server-side encryption to protect your data at rest and client-side encryption to protect your data in transit.

Note

To increase database security, we recommend that you use AWS Secrets Manager instead of environment variables to store database credentials. For more information, see [Use Secrets Manager secrets in Lambda functions](#).

Security at rest

Lambda always provides server-side encryption at rest with an AWS KMS key. By default, Lambda uses an AWS managed key. If this default behavior suits your workflow, you don't need to set up anything else. Lambda creates the AWS managed key in your account and manages the permissions for you. AWS doesn't charge you to use this key.

If you prefer, you can provide an AWS KMS customer managed key instead. You might do this to have control over rotation of the KMS key or to meet the requirements of your organization for managing KMS keys. When you use a customer managed key, only users in your account with access to the KMS key can view or manage environment variables on the function.

Customer managed keys incur standard AWS KMS charges. For more information, see [AWS Key Management Service pricing](#).

Security in transit

For additional security, you can enable helpers for encryption in transit, which ensures that your environment variables are encrypted client-side for protection in transit.

To configure encryption for your environment variables

1. Use the AWS Key Management Service (AWS KMS) to create any customer managed keys for Lambda to use for server-side and client-side encryption. For more information, see [Creating keys](#) in the *AWS Key Management Service Developer Guide*.
2. Using the Lambda console, navigate to the **Edit environment variables** page.
 - a. Open the [Functions page](#) of the Lambda console.
 - b. Choose a function.
 - c. Choose **Configuration**, then choose **Environment variables** from the left navigation bar.
 - d. In the **Environment variables** section, choose **Edit**.
 - e. Expand **Encryption configuration**.
3. (Optional) Enable console encryption helpers to use client-side encryption to protect your data in transit.
 - a. Under **Encryption in transit**, choose **Enable helpers for encryption in transit**.
 - b. For each environment variable that you want to enable console encryption helpers for, choose **Encrypt** next to the environment variable.
 - c. Under AWS KMS key to encrypt in transit, choose a customer managed key that you created at the beginning of this procedure.
 - d. Choose **Execution role policy** and copy the policy. This policy grants permission to your function's execution role to decrypt the environment variables.

Save this policy to use in the last step of this procedure.
 - e. Add code to your function that decrypts the environment variables. To see an example, choose **Decrypt secrets snippet**.
4. (Optional) Specify your customer managed key for encryption at rest.
 - a. Choose **Use a customer master key**.
 - b. Choose a customer managed key that you created at the beginning of this procedure.

5. Choose **Save**.

6. Set up permissions.

If you're using a customer managed key with server-side encryption, grant permissions to any users or roles that you want to be able to view or manage environment variables on the function. For more information, see [Managing permissions to your server-side encryption KMS key](#).

If you're enabling client-side encryption for security in transit, your function needs permission to call the `kms:Decrypt` API operation. Add the policy that you saved previously in this procedure to the function's [execution role](#).

Managing permissions to your server-side encryption KMS key

No AWS KMS permissions are required for your user or the function's execution role to use the default encryption key. To use a customer managed key, you need permission to use the key. Lambda uses your permissions to create a grant on the key. This allows Lambda to use it for encryption.

- `kms:ListAliases` – To view keys in the Lambda console.
- `kms:CreateGrant`, `kms:Encrypt` – To configure a customer managed key on a function.
- `kms:Decrypt` – To view and manage environment variables that are encrypted with a customer managed key.

You can get these permissions from your AWS account or from a key's resource-based permissions policy. `ListAliases` is provided by the [managed policies for Lambda](#). Key policies grant the remaining permissions to users in the **Key users** group.

Users without `Decrypt` permissions can still manage functions, but they can't view environment variables or manage them in the Lambda console. To prevent a user from viewing environment variables, add a statement to the user's permissions that denies access to the default key, a customer managed key, or all keys.

Example IAM policy – Deny access by key ARN

JSON

```
{
```

```
"Version": "2012-10-17",

]
```

For details on managing key permissions, see [Key policies in AWS KMS](#) in the *AWS Key Management Service Developer Guide*.

Giving Lambda functions access to resources in an Amazon VPC

With Amazon Virtual Private Cloud (Amazon VPC), you can create private networks in your AWS account to host resources such as Amazon Elastic Compute Cloud (Amazon EC2) instances, Amazon Relational Database Service (Amazon RDS) instances, and Amazon ElastiCache instances. You can give your Lambda function access to resources hosted in an Amazon VPC by attaching your function to the VPC through the private subnets that contain the resources. Follow the instructions in the following sections to attach a Lambda function to an Amazon VPC using the Lambda console, the AWS Command Line Interface (AWS CLI), or AWS SAM.

Note

Every Lambda function runs inside a VPC that is owned and managed by the Lambda service. These VPCs are maintained automatically by Lambda and are not visible to customers. Configuring your function to access other AWS resources in an Amazon VPC has no effect on the Lambda-managed VPC your function runs inside.

Sections

- [Required IAM permissions](#)
- [Attaching Lambda functions to an Amazon VPC in your AWS account](#)
- [Internet access when attached to a VPC](#)
- [IPv6 support](#)
- [Best practices for using Lambda with Amazon VPCs](#)
- [Understanding Hyperplane Elastic Network Interfaces \(ENIs\)](#)
- [Using IAM condition keys for VPC settings](#)
- [VPC tutorials](#)

Required IAM permissions

To attach a Lambda function to an Amazon VPC in your AWS account, Lambda needs permissions to create and manage the network interfaces it uses to give your function access to the resources in the VPC.

The network interfaces that Lambda creates are known as Hyperplane Elastic Network Interfaces, or Hyperplane ENIs. To learn more about these network interfaces, see [the section called “Understanding Hyperplane Elastic Network Interfaces \(ENIs\)”](#).

You can give your function the permissions it needs by attaching the AWS managed policy [AWSLambdaVPCAccessExecutionRole](#) to your function's execution role. When you create a new function in the Lambda console and attach it to a VPC, Lambda automatically adds this permissions policy for you.

If you prefer to create your own IAM permissions policy, make sure to add all of the following permissions and allow them on all resources ("Resource": "*"):

- `ec2:CreateNetworkInterface`
- `ec2:DescribeNetworkInterfaces`
- `ec2:DescribeSubnets`
- `ec2>DeleteNetworkInterface`
- `ec2:AssignPrivateIpAddresses`
- `ec2:UnassignPrivateIpAddresses`

Note that your function's role only needs these permissions to create the network interfaces, not to invoke your function. You can still invoke your function successfully when it's attached to an Amazon VPC, even if you remove these permissions from your function's execution role.

To attach your function to a VPC, Lambda also needs to verify network resources using your IAM user role. Ensure that your user role has the following IAM permissions:

- **`ec2:DescribeSecurityGroups`**
- **`ec2:DescribeSubnets`**
- **`ec2:DescribeVpcs`**
- **`ec2:GetSecurityGroupsForVpc`**

Note

The Amazon EC2 permissions that you grant to your function's execution role are used by the Lambda service to attach your function to a VPC. However, you're also implicitly

granting these permissions to your function's code. This means that your function code is able to make these Amazon EC2 API calls. For advice on following security best practices, see [the section called "Security best practices"](#).

Attaching Lambda functions to an Amazon VPC in your AWS account

Attach your function to an Amazon VPC in your AWS account by using the Lambda console, the AWS CLI or AWS SAM. If you're using the AWS CLI or AWS SAM, or attaching an existing function to a VPC using the Lambda console, make sure that your function's execution role has the necessary permissions listed in the previous section.

Lambda functions can't connect directly to a VPC with [dedicated instance tenancy](#). To connect to resources in a dedicated VPC, [peer it to a second VPC with default tenancy](#).

Lambda console

To attach a function to an Amazon VPC when you create it

1. Open the [Functions page](#) of the Lambda console and choose **Create function**.
2. Under **Basic information**, for **Function name**, enter a name for your function.
3. Configure VPC settings for the function by doing the following:
 - a. Expand **Advanced settings**.
 - b. Select **Enable VPC**, and then select the VPC you want to attach the function to.
 - c. (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
 - d. Choose the subnets and security groups to create the network interface for. If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

Note

To access private resources, connect your function to private subnets. If your function needs internet access, see [the section called "Internet access for VPC functions"](#). Connecting a function to a public subnet doesn't give it internet access or a public IP address.

4. Choose **Create function**.

To attach an existing function to an Amazon VPC

1. Open the [Functions page](#) of the Lambda console and select your function.
2. Choose the **Configuration** tab, then choose **VPC**.
3. Choose **Edit**.
4. Under **VPC**, select the Amazon VPC you want to attach your function to.
5. (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
6. Choose the subnets and security groups to create the network interface for. If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

Note

To access private resources, connect your function to private subnets. If your function needs internet access, see [the section called "Internet access for VPC functions"](#). Connecting a function to a public subnet doesn't give it internet access or a public IP address.

7. Choose **Save**.

AWS CLI

To attach a function to an Amazon VPC when you create it

- To create a Lambda function and attach it to a VPC, run the following CLI create-function command.

```
aws lambda create-function --function-name my-function \  
--runtime nodejs24.x --handler index.js --zip-file fileb://function.zip \  
--role arn:aws:iam::123456789012:role/lambda-role \  
--vpc-config  
  Ipv6AllowedForDualStack=true, SubnetIds=subnet-071f712345678e7c8,subnet-07fd123456788a03
```

Specify your own subnets and security groups and set `Ipv6AllowedForDualStack` to `true` or `false` according to your use case.

To attach an existing function to an Amazon VPC

- To attach an existing function to a VPC, run the following CLI update-function-configuration command.

```
aws lambda update-function-configuration --function-name my-function \
--vpc-config Ipv6AllowedForDualStack=true,
SubnetIds=subnet-071f712345678e7c8,subnet-07fd123456788a036,SecurityGroupIds=sg-0859123
```

To unattach your function from a VPC

- To unattach your function from a VPC, run the following update-function-configurationCLI command with an empty list of VPC subnets and security groups.

```
aws lambda update-function-configuration --function-name my-function \
--vpc-config SubnetIds=[],SecurityGroupIds=[]
```

AWS SAM

To attach your function to a VPC

- To attach a Lambda function to an Amazon VPC, add the VpcConfig property to your function definition as shown in the following example template. For more information about this property, see [AWS::Lambda::Function VpcConfig](#) in the *CloudFormation User Guide* (the AWS SAM VpcConfig property is passed directly to the VpcConfig property of an CloudFormation AWS::Lambda::Function resource).

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: AWS::Serverless-2016-10-31

Resources:
  MyFunction:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: ./lambda_function/
      Handler: lambda_function.handler
      Runtime: python3.12
      VpcConfig:
        SecurityGroupIds:
```

```
- !Ref MySecurityGroup
SubnetIds:
  - !Ref MySubnet1
  - !Ref MySubnet2
Policies:
  - AWSLambdaVPCLambdaAccessExecutionRole

MySecurityGroup:
  Type: AWS::EC2::SecurityGroup
  Properties:
    GroupDescription: Security group for Lambda function
    VpcId: !Ref MyVPC

MySubnet1:
  Type: AWS::EC2::Subnet
  Properties:
    VpcId: !Ref MyVPC
    CidrBlock: 10.0.1.0/24

MySubnet2:
  Type: AWS::EC2::Subnet
  Properties:
    VpcId: !Ref MyVPC
    CidrBlock: 10.0.2.0/24

MyVPC:
  Type: AWS::EC2::VPC
  Properties:
    CidrBlock: 10.0.0.0/16
```

For more information about configuring your VPC in AWS SAM, see [AWS::EC2::VPC](#) in the *CloudFormation User Guide*.

Internet access when attached to a VPC

By default, Lambda functions have access to the public internet. When you attach your function to a VPC, it can only access resources available within that VPC. To give your function access to the internet, you also need to configure the VPC to have internet access. To learn more, see [the section called “Internet access for VPC functions”](#).

IPv6 support

Your function can connect to resources in dual-stack VPC subnets over IPv6. This option is turned off by default. To allow outbound IPv6 traffic, use the console or the `--vpc-config Ipv6AllowedForDualStack=true` option with the [create-function](#) or [update-function-configuration](#) command.

Note

To allow outbound IPv6 traffic in a VPC, all of the subnets that are connected to the function must be dual-stack subnets. Lambda doesn't support outbound IPv6 connections for IPv6-only subnets in a VPC or outbound IPv6 connections for functions that are not connected to a VPC.

You can update your function code to explicitly connect to subnet resources over IPv6. The following Python example opens a socket and connects to an IPv6 server.

Example — Connect to IPv6 server

```
def connect_to_server(event, context):
    server_address = event['host']
    server_port = event['port']
    message = event['message']
    run_connect_to_server(server_address, server_port, message)

def run_connect_to_server(server_address, server_port, message):
    sock = socket.socket(socket.AF_INET6, socket.SOCK_STREAM, 0)
    try:
        # Send data
        sock.connect((server_address, int(server_port), 0, 0))
        sock.sendall(message.encode())
        BUFF_SIZE = 4096
        data = b''
        while True:
            segment = sock.recv(BUFF_SIZE)
            data += segment
            # Either 0 or end of data
            if len(segment) < BUFF_SIZE:
                break
    return data
```

```
finally:
    sock.close()
```

Best practices for using Lambda with Amazon VPCs

To ensure that your Lambda VPC configuration meets best practice guidelines, follow the advice in the following sections.

Security best practices

To attach your Lambda function to a VPC, you need to give your function's execution role a number of Amazon EC2 permissions. These permissions are required to create the network interfaces your function uses to access the resources in the VPC. However, these permissions are also implicitly granted to your function's code. This means that your function code has permission to make these Amazon EC2 API calls.

To follow the principle of least-privilege access, add a deny policy like the following example to your function's execution role. This policy prevents your function code from making calls to the Amazon EC2 APIs, while still allowing the Lambda service to manage VPC resources on your behalf. The policy uses the `lambda:SourceFunctionArn` condition key, which only applies to API calls made by your function code during execution. For more information, see [the section called "Source function ARN"](#).

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Deny",
      "Action": [
        "ec2:CreateNetworkInterface",
        "ec2:DeleteNetworkInterface",
        "ec2:DescribeNetworkInterfaces",
        "ec2:DescribeSubnets",
        "ec2:DetachNetworkInterface",
        "ec2:AssignPrivateIpAddresses",
        "ec2:UnassignPrivateIpAddresses"
      ],

            "lambda:SourceFunctionArn": [
                "arn:aws:lambda:us-
west-2:123456789012:function:my_function"
            ]
        }
    }
}

```

AWS provides [security groups](#) and [network Access Control Lists \(ACLs\)](#) to increase security in your VPC. Security groups control inbound and outbound traffic for your resources, and network ACLs control inbound and outbound traffic for your subnets. Security groups provide enough access control for most subnets. You can use network ACLs if you want an additional layer of security for your VPC. For general guidelines on security best practices when using Amazon VPCs, see [Security best practices for your VPC](#) in the *Amazon Virtual Private Cloud User Guide*.

Performance best practices

When you attach your function to a VPC, Lambda checks to see if there is an available network resource (Hyperplane ENI) it can use to connect to. Hyperplane ENIs are associated with a particular combination of security groups and VPC subnets. If you've already attached one function to a VPC, specifying the same subnets and security groups when you attach another function means that Lambda can share the network resources and avoid the need to create a new Hyperplane ENI. For more information about Hyperplane ENIs and their lifecycle, see [the section called "Understanding Hyperplane Elastic Network Interfaces \(ENIs\)"](#).

Understanding Hyperplane Elastic Network Interfaces (ENIs)

A Hyperplane ENI is a managed resource that acts as a network interface between your Lambda function and the resources you want your function to connect to. The Lambda service creates and manages these ENIs automatically when you attach your function to a VPC.

Hyperplane ENIs are not directly visible to you, and you don't need to configure or manage them. However, knowing how they work can help you to understand your function's behavior when you attach it to a VPC.

The first time you attach a function to a VPC using a particular subnet and security group combination, Lambda creates a Hyperplane ENI. Other functions in your account that use the

same subnet and security group combination can also use this ENI. Wherever possible, Lambda reuses existing ENIs to optimize resource utilization and minimize the creation of new ENIs. Each Hyperplane ENI supports up to 65,000 connections/ports. If the number of connections exceeds this limit, Lambda scales the number of ENIs automatically based on network traffic and concurrency requirements.

For new functions, while Lambda is creating a Hyperplane ENI, your function remains in the Pending state and you can't invoke it. Your function transitions to the Active state only when the Hyperplane ENI is ready, which can take several minutes. For existing functions, you can't perform additional operations that target the function, such as creating versions or updating the function's code, but you can continue to invoke previous versions of the function.

As part of managing the ENI lifecycle, Lambda may delete and recreate ENIs to load balance network traffic across ENIs or to address issues found in ENI health-checks. Additionally, if a Lambda function remains idle for 14 days, Lambda reclaims any unused Hyperplane ENIs and sets the function state to `Inactive`. The next invocation attempt will fail, and the function re-enters the Pending state until Lambda completes the creation or allocation of a Hyperplane ENI. We recommend that your design doesn't rely on the persistence of ENIs.

When you update a function to remove its VPC configuration, Lambda requires up to 20 minutes to delete the attached Hyperplane ENI. Lambda only deletes the ENI if no other function (or published function version) is using that Hyperplane ENI.

Lambda relies on permissions in the function [execution role](#) to delete the Hyperplane ENI. If you delete the execution role before Lambda deletes the Hyperplane ENI, Lambda won't be able to delete the Hyperplane ENI. You can manually perform the deletion.

Using IAM condition keys for VPC settings

You can use Lambda-specific condition keys for VPC settings to provide additional permission controls for your Lambda functions. For example, you can require that all functions in your organization are connected to a VPC. You can also specify the subnets and security groups that the function's users can and can't use.

Lambda supports the following condition keys in IAM policies:

- **lambda:VpcIds** – Allow or deny one or more VPCs.
- **lambda:SubnetIds** – Allow or deny one or more subnets.
- **lambda:SecurityGroupIds** – Allow or deny one or more security groups.

The Lambda API operations [CreateFunction](#) and [UpdateFunctionConfiguration](#) support these condition keys. For more information about using condition keys in IAM policies, see [IAM JSON Policy Elements: Condition](#) in the *IAM User Guide*.

Tip

If your function already includes a VPC configuration from a previous API request, you can send an `UpdateFunctionConfiguration` request without the VPC configuration.

Example policies with condition keys for VPC settings

The following examples demonstrate how to use condition keys for VPC settings. After you create a policy statement with the desired restrictions, append the policy statement for the target user or role.

Ensure that users deploy only VPC-connected functions

To ensure that all users deploy only VPC-connected functions, you can deny function create and update operations that don't include a valid VPC ID.

Note that VPC ID is not an input parameter to the `CreateFunction` or `UpdateFunctionConfiguration` request. Lambda retrieves the VPC ID value based on the subnet and security group parameters.

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "EnforceVPCFunction",
      "Action": [
        "lambda:CreateFunction",
        "lambda:UpdateFunctionConfiguration"
      ],
      "Effect": "Deny",
      "Resource": "*",
      "Condition": {
        "Null": {
          "lambda:VpcIds": "true"
        }
      }
    }
  ]
}
```

```

    }
  }
]
}

```

Deny users access to specific VPCs, subnets, or security groups

To deny users access to specific VPCs, use `StringEquals` to check the value of the `lambda:VpcIds` condition. The following example denies users access to `vpc-1` and `vpc-2`.

JSON

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "EnforceOutOfVPC",
      "Action": [
        "lambda:CreateFunction",
        "lambda:UpdateFunctionConfiguration"
      ],
      "Effect": "Deny",
      "Resource": "*",
      "Condition": {
        "StringEquals": {
          "lambda:VpcIds": [
            "vpc-1",
            "vpc-2"
          ]
        }
      }
    }
  ]
}

```

To deny users access to specific subnets, use `StringEquals` to check the value of the `lambda:SubnetIds` condition. The following example denies users access to `subnet-1` and `subnet-2`.

```
{
  "Sid": "EnforceOutOfSubnet",
  "Action": [
    "lambda:CreateFunction",
    "lambda:UpdateFunctionConfiguration"
  ],
  "Effect": "Deny",
  "Resource": "*",
  "Condition": {
    "ForAnyValue:StringEquals": {
      "lambda:SubnetIds": ["subnet-1", "subnet-2"]
    }
  }
}
```

To deny users access to specific security groups, use `StringEquals` to check the value of the `lambda:SecurityGroupIds` condition. The following example denies users access to `sg-1` and `sg-2`.

```
{
  "Sid": "EnforceOutOfSecurityGroups",
  "Action": [
    "lambda:CreateFunction",
    "lambda:UpdateFunctionConfiguration"
  ],
  "Effect": "Deny",
  "Resource": "*",
  "Condition": {
    "ForAnyValue:StringEquals": {
      "lambda:SecurityGroupIds": ["sg-1", "sg-2"]
    }
  }
}
```

Allow users to create and update functions with specific VPC settings

To allow users to access specific VPCs, use `StringEquals` to check the value of the `lambda:VpcIds` condition. The following example allows users to access `vpc-1` and `vpc-2`.

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "EnforceStayInSpecificVpc",
      "Action": [
        "lambda:CreateFunction",
        "lambda:UpdateFunctionConfiguration"
      ],
      "Effect": "Allow",
      "Resource": "*",
      "Condition": {
        "StringEquals": {
          "lambda:VpcIds": [
            "vpc-1",
            "vpc-2"
          ]
        }
      }
    }
  ]
}
```

To allow users to access specific subnets, use `StringEquals` to check the value of the `lambda:SubnetIds` condition. The following example allows users to access subnet-1 and subnet-2.

```
{
  "Sid": "EnforceStayInSpecificSubnets",
  "Action": [
    "lambda:CreateFunction",
    "lambda:UpdateFunctionConfiguration"
  ],
  "Effect": "Allow",
  "Resource": "*",
  "Condition": {
    "ForAllValues:StringEquals": {
      "lambda:SubnetIds": ["subnet-1", "subnet-2"]
    }
  }
}
```

```
}  
}
```

To allow users to access specific security groups, use `StringEquals` to check the value of the `lambda:SecurityGroupIds` condition. The following example allows users to access `sg-1` and `sg-2`.

```
{  
  "Sid": "EnforceStayInSpecificSecurityGroup",  
  "Action": [  
    "lambda:CreateFunction",  
    "lambda:UpdateFunctionConfiguration"  
  ],  
  "Effect": "Allow",  
  "Resource": "*",  
  "Condition": {  
    "ForAllValues:StringEquals": {  
      "lambda:SecurityGroupIds": ["sg-1", "sg-2"]  
    }  
  }  
}
```

VPC tutorials

In the following tutorials, you connect a Lambda function to resources in your VPC.

- [Tutorial: Using a Lambda function to access Amazon RDS in an Amazon VPC](#)
- [Tutorial: Configuring a Lambda function to access Amazon ElastiCache in an Amazon VPC](#)

Giving Lambda functions access to a resource in an Amazon VPC in another account

You can give your AWS Lambda function access to a resource in a Amazon VPC in Amazon Virtual Private Cloud managed by another account, without exposing either VPC to the internet. This access pattern allows you to share data with other organizations using AWS. Using this access pattern, you can share data between VPCs with a greater level of security and performance than over the internet. Configure your Lambda function to use a Amazon VPC peering connection to access these resources.

Warning

When you allow access between accounts or VPCs, check that your plan meets the security requirements of the respective organizations that manage these accounts. Following the instructions in this document will affect the security posture of your resources.

In this tutorial, you connect two accounts together with a peering connection using IPv4. You configure a Lambda function that is not already connected to a Amazon VPC. You configure DNS resolution to connect your function to resources that do not provide static IPs. To adapt these instructions to other peering scenarios, consult the [VPC Peering Guide](#).

Prerequisites

To give a Lambda function access to a resource in another account, you must have:

- A Lambda function, configured to authenticate with and then read from your resource.
- A resource in another account, such as an Amazon RDS cluster, available through Amazon VPC.
- Credentials for your Lambda function's account and your resource's account. If you are not authorized to use your resource's account, contact an authorized user to prepare that account.
- Permission to create and update a VPC (and supporting Amazon VPC resources) to associate with your Lambda function.
- Permission to update the execution role and VPC configuration for your Lambda function.
- Permission to create a VPC peering connection in your Lambda function's account.
- Permission to accept a VPC peering connection in your resource's account.

- Permission to update the configuration of your resource's VPC (and supporting Amazon VPC resources).
- Permission to invoke your Lambda function.

Create an Amazon VPC in your function's account

Create an Amazon VPC, subnets, route tables, and a security group in your Lambda function's account.

To create a VPC, subnets, and other VPC resources using the console

1. Open the Amazon VPC Console at <https://console.aws.amazon.com/vpc/>.
2. On the dashboard, choose **Create VPC**.
3. For **IPv4 CIDR block**, provide a private CIDR block. Your CIDR block must not overlap with blocks used in your resource's VPC. Don't pick a block your resources' VPC uses to assign IPs to resources or a block already defined in the route tables in your resources VPC. For more information about defining appropriate CIDR blocks, see [VPC CIDR blocks](#).
4. Choose **Customize AZs**.
5. Select the same AZs as your resource.
6. For **Number of public subnets**, choose **0**.
7. For **VPC endpoints**, choose **None**.
8. Choose **Create VPC**.

Grant VPC permissions to your function's execution role

Attach [AWSLambdaVPCAccessExecutionRole](#) to your function's execution role to allow it to connect to VPCs.

To grant VPC permissions to your function's execution role

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function.
3. Choose **Configuration**.
4. Choose **Permissions**.
5. Under **Role name**, choose the execution role.

6. In the **Permissions policies** section, choose **Add permissions**.
7. In the dropdown list, choose **Attach policies**.
8. In the search box, enter `AWSLambdaVPCAccessExecutionRole`.
9. To the left of the policy name, choose the checkbox.
10. Choose **Add permissions**.

To attach your function to your Amazon VPC

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function.
3. Choose the **Configuration** tab, then choose **VPC**.
4. Choose **Edit**.
5. Under **VPC**, select your VPC.
6. Under **Subnets**, choose your subnets.
7. Under **Security groups**, choose the default security group for your VPC.
8. Choose **Save**.

Create a VPC peering connection request

Create a VPC peering connection request from your function's VPC (the requester VPC) to your resource's VPC (the acceptor VPC).

To request a VPC peering connection from your function's VPC

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Peering connections**.
3. Choose **Create peering connection**.
4. For **VPC ID (Requester)**, select your function's VPC.
5. For **Account ID**, enter the ID of your resource's account.
6. For **VPC ID (Acceptor)**, enter your resource's VPC.

Prepare your resource's account

To create your peering connection and prepare your resource's VPC to use the connection, log in to your resource's account with a role that holds the permissions listed in the prerequisites. The steps to log in may be different based on how the account is secured. For more information about how to sign in to an AWS account, see the [AWS Sign-in User Guide](#). In your resource's account, perform the following procedures.

To accept the VPC peering connection request

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Peering connections**.
3. Select the pending VPC peering connection (the status is pending-acceptance).
4. Choose **Actions**
5. From the dropdown list, choose **Accept request**.
6. When prompted for confirmation, choose **Accept request**.
7. Choose **Modify my route tables now** to add a route to the main route table for your VPC so that you can send and receive traffic across the peering connection.

Inspect the route tables for the resource's VPC. The route generated by Amazon VPC might not establish connectivity, based on how your resource's VPC is set up. Check for conflicts between the new route and existing configuration for the VPC. For more information about troubleshooting, see [Troubleshoot a VPC peering connection](#) in the *Amazon Virtual Private Cloud VPC Peering Guide*.

To update the security group for your resource

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Security groups**.
3. Select the security group for your resource.
4. Choose **Actions**.
5. From the dropdown list, choose **Edit inbound rules**.
6. Choose **Add rule**.
7. For **Source** enter your function's account ID and security group ID, separated by a forward slash (for example, 111122223333/sg-1a2b3c4d).
8. Choose **Edit outbound rules**.

9. Check whether outbound traffic is restricted. Default VPC settings allow all outbound traffic. If outbound traffic is restricted, continue to the next step.
10. Choose **Add rule**.
11. For **Destination** enter your function's account ID and security group ID, separated by a forward slash (for example, 111122223333/sg-1a2b3c4d).
12. Choose **Save rules**.

To enable DNS resolution for your peering connection

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Peering connections**.
3. Select your peering connection.
4. Choose **Actions**.
5. Choose **Edit DNS settings**.
6. Below **Accepter DNS resolution**, select **Allow requester VPC to resolve DNS of accepter VPC hosts to private IP**.
7. Choose **Save changes**.

Update VPC configuration in your function's account

Log in to your function's account, then update the VPC configuration.

To add a route for your VPC peering connection

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Route tables**.
3. Select the check box next to the name of the route table for the subnet you associated with your function.
4. Choose **Actions**.
5. Choose **Edit routes**.
6. Choose **Add route**.
7. For **Destination**, enter the CIDR block for your resource's VPC.
8. For **Target**, select your VPC peering connection.
9. Choose **Save changes**.

For more information about considerations you may encounter while updating your route tables, consult [Update your route tables for a VPC peering connection](#).

To update the security group for your Lambda function

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Security groups**.
3. Choose **Actions**.
4. Choose **Edit inbound rules**.
5. Choose **Add rule**.
6. For **Source** enter your resource's account ID and security group ID, separated by a forward slash (for example, 111122223333/sg-1a2b3c4d).
7. Choose **Save rules**.

To enable DNS resolution for your peering connection

1. Open the <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Peering connections**.
3. Select your peering connection.
4. Choose **Actions**.
5. Choose **Edit DNS settings**.
6. Below **Requester DNS resolution**, select **Allow accepter VPC to resolve DNS of requester VPC hosts to private IP**.
7. Choose **Save changes**.

Test your function

To create a test event and inspect your function's output

1. In the **Code source** pane, choose **Test**.
2. Select **Create new event**.
3. In the **Event JSON** panel, replace the default values with an input appropriate for your Lambda function.
4. Choose **Invoke**.

5. In the **Execution results** tab, confirm that **Response** contains your expected output.

Additionally, you can check your function's logs to verify the logs are as you expect.

To view your function's invocation records in CloudWatch Logs

1. Choose the **Monitor** tab.
2. Choose **View CloudWatch logs**.
3. In the **Log streams** tab, choose the log stream for your function's invocation.
4. Confirm your logs are as you expect.

Enable internet access for VPC-connected Lambda functions

By default, Lambda functions run in a Lambda-managed VPC that has internet access. To access resources in a VPC in your account, you can add a VPC configuration to a function. This restricts the function to resources within that VPC, unless the VPC has internet access. This page explains how to provide internet access to VPC-connected Lambda functions.

I don't have a VPC yet

Create the VPC

The **Create VPC workflow** creates all VPC resources required for a Lambda function to access the public internet from a private subnet, including subnets, NAT gateway, internet gateway, and route table entries.

To create the VPC

1. Open the Amazon VPC console at <https://console.aws.amazon.com/vpc/>.
2. On the dashboard, choose **Create VPC**.
3. For **Resources to create**, choose **VPC and more**.
4. **Configure the VPC**
 - a. For **Name tag auto-generation**, enter a name for the VPC.
 - b. For **IPv4 CIDR block**, you can keep the default suggestion, or alternatively you can enter the CIDR block required by your application or network.
 - c. If your application communicates by using IPv6 addresses, choose **IPv6 CIDR block, Amazon-provided IPv6 CIDR block**.
5. **Configure the subnets**
 - a. For **Number of Availability Zones**, choose **2**. We recommend at least two AZs for high availability.
 - b. For **Number of public subnets**, choose **2**.
 - c. For **Number of private subnets**, choose **2**.
 - d. You can keep the default CIDR block for the public subnet, or alternatively you can expand **Customize subnet CIDR blocks** and enter a CIDR block. For more information, see [Subnet CIDR blocks](#).
6. For **NAT gateways**, choose **1 per AZ** to improve resiliency.

7. For **Egress only internet gateway**, choose **Yes** if you opted to include an IPv6 CIDR block.
8. For **VPC endpoints**, keep the default (**S3 Gateway**). There is no cost for this option. For more information, see [Types of VPC endpoints for Amazon S3](#).
9. For **DNS options**, keep the default settings.
10. Choose **Create VPC**.

Configure the Lambda function

To configure a VPC when you create a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Under **Basic information**, for **Function name**, enter a name for your function.
4. Expand **Advanced settings**.
5. Select **Enable VPC**, and then choose a VPC.
6. (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
7. For **Subnets**, select all private subnets. The private subnets can access the internet through the NAT gateway. Connecting a function to a public subnet doesn't give it internet access.

Note

If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

8. For **Security groups**, select a security group that allows outbound traffic.
9. Choose **Create function**.

Lambda automatically creates an execution role with the [AWSLambdaVPCAccessExecutionRole](#) AWS managed policy. The permissions in this policy are required only to create elastic network interfaces for the VPC configuration, not to invoke your function. To apply least-privilege permissions, you can remove the **AWSLambdaVPCAccessExecutionRole** policy from your execution role after you create the function and VPC configuration. For more information, see [Required IAM permissions](#).

To configure a VPC for an existing function

To add a VPC configuration to an existing function, the function's execution role must have [permission to create and manage elastic network interfaces](#). The [AWSLambdaVPCAccessExecutionRole](#) AWS managed policy includes the required permissions. To apply least-privilege permissions, you can remove the **AWSLambdaVPCAccessExecutionRole** policy from your execution role after you create the VPC configuration.

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab, and then choose **VPC**.
4. Under **VPC**, choose **Edit**.
5. Select the VPC.
6. (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
7. For **Subnets**, select all private subnets. The private subnets can access the internet through the NAT gateway. Connecting a function to a public subnet doesn't give it internet access.

Note

If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

8. For **Security groups**, select a security group that allows outbound traffic.
9. Choose **Save**.

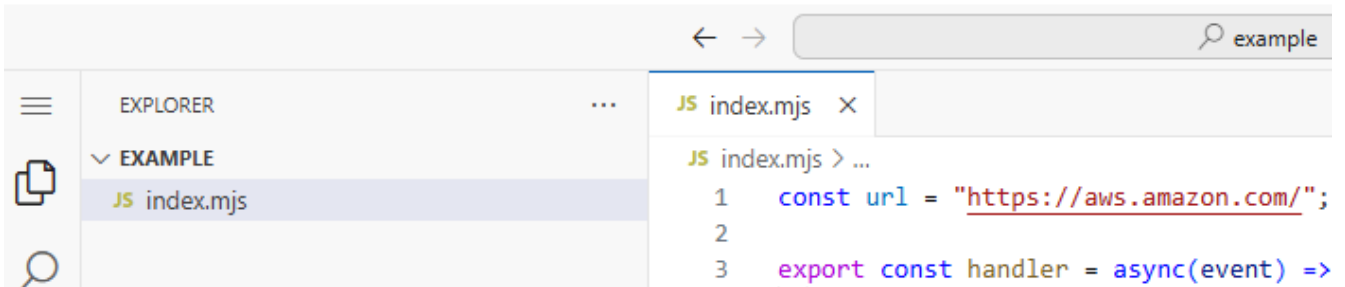

Test the function

Use the following sample code to confirm that your VPC-connected function can reach the public internet. If successful, the code returns a 200 status code. If unsuccessful, the function times out.

Node.js

1. In the **Code source** pane on the Lambda console, paste the following code into the **index.mjs** file. The function makes an HTTP GET request to a public endpoint and returns the HTTP response code to test if the function has access to the public internet.

Code source [Info](#)

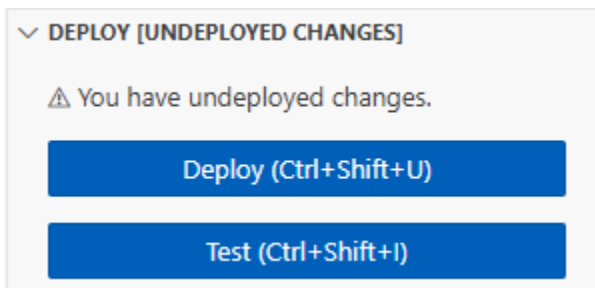

Example — HTTP request with async/await

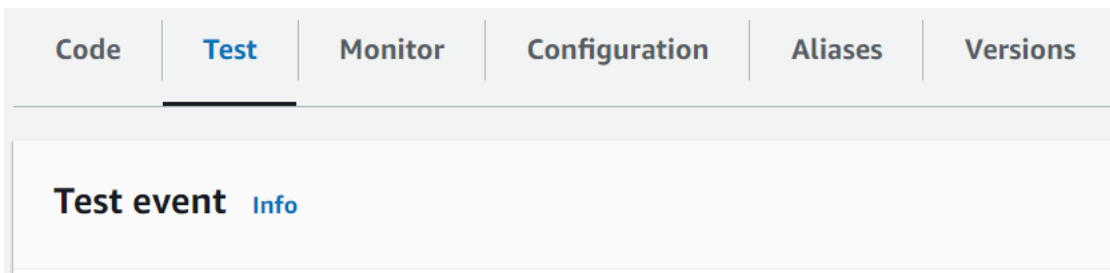

```
const url = "https://aws.amazon.com/";

export const handler = async(event) => {
  try {
    const res = await fetch(url);
    console.info("status", res.status);
    return res.status;
  }
  catch (e) {
    console.error(e);
    return 500;
  }
};
```

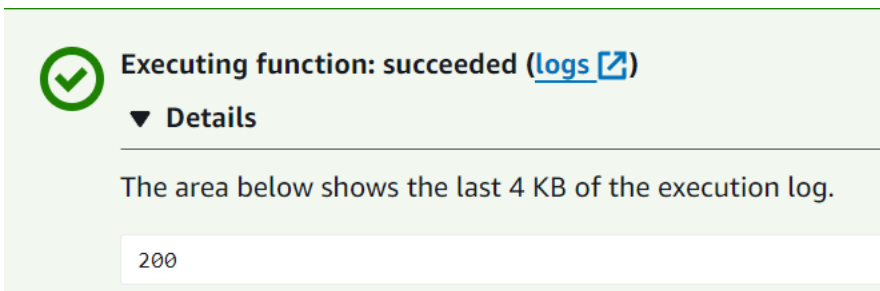

2. In the **DEPLOY** section, choose **Deploy** to update your function's code:

3. Choose the **Test** tab.

4. Choose **Test**.
5. The function returns a 200 status code. This means that the function has outbound internet access.

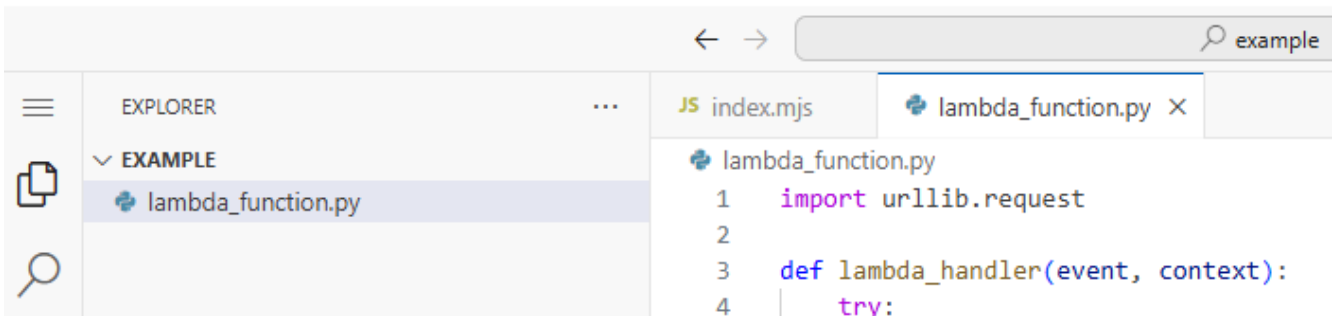

If the function can't reach the public internet, you get an error message like this:

```
{
  "errorMessage": "2024-04-11T17:22:20.857Z abe12jlc-640a-8157-0249-9be825c2y110
Task timed out after 3.01 seconds"
}
```

Python

1. In the **Code source** pane on the Lambda console, paste the following code into the **lambda_function.py** file. The function makes an HTTP GET request to a public endpoint and returns the HTTP response code to test if the function has access to the public internet.

Code source [Info](#)

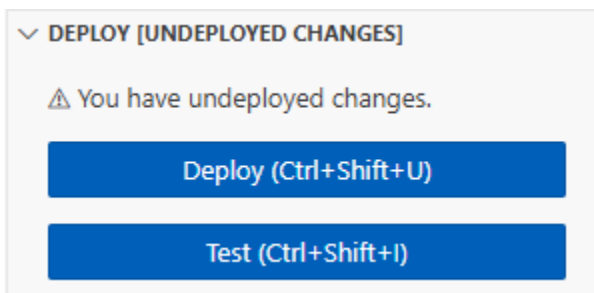

```

import urllib.request

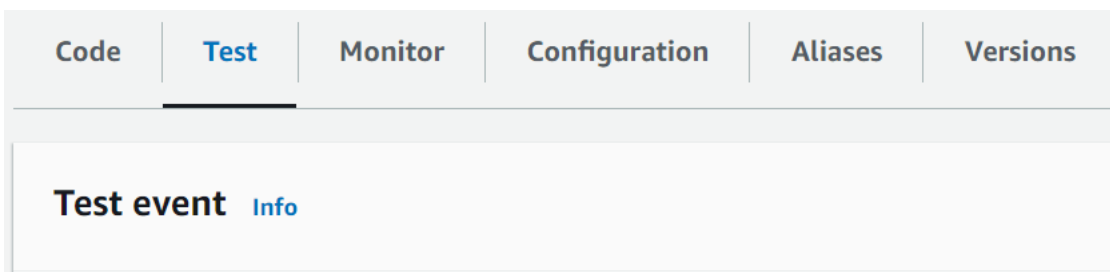

def lambda_handler(event, context):
    try:
        response = urllib.request.urlopen('https://aws.amazon.com')
        status_code = response.getcode()
        print('Response Code:', status_code)
        return status_code
    except Exception as e:
        print('Error:', e)
        raise e

```

- In the **DEPLOY** section, choose **Deploy** to update your function's code:

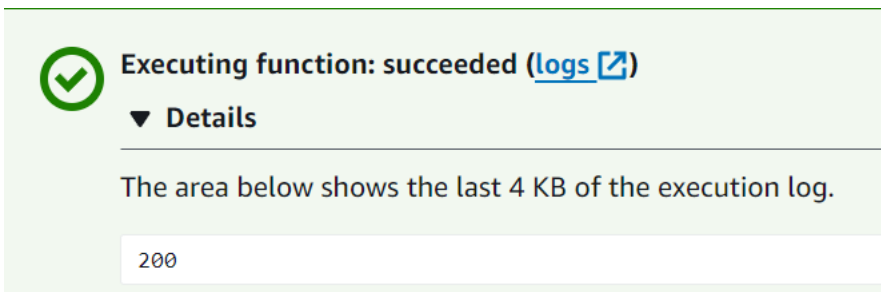

- Choose the **Test** tab.

- Choose **Test**.

- The function returns a 200 status code. This means that the function has outbound internet access.

If the function can't reach the public internet, you get an error message like this:

```
{
  "errorMessage": "2024-04-11T17:22:20.857Z abe12jlc-640a-8157-0249-9be825c2y110
  Task timed out after 3.01 seconds"
}
```

I already have a VPC

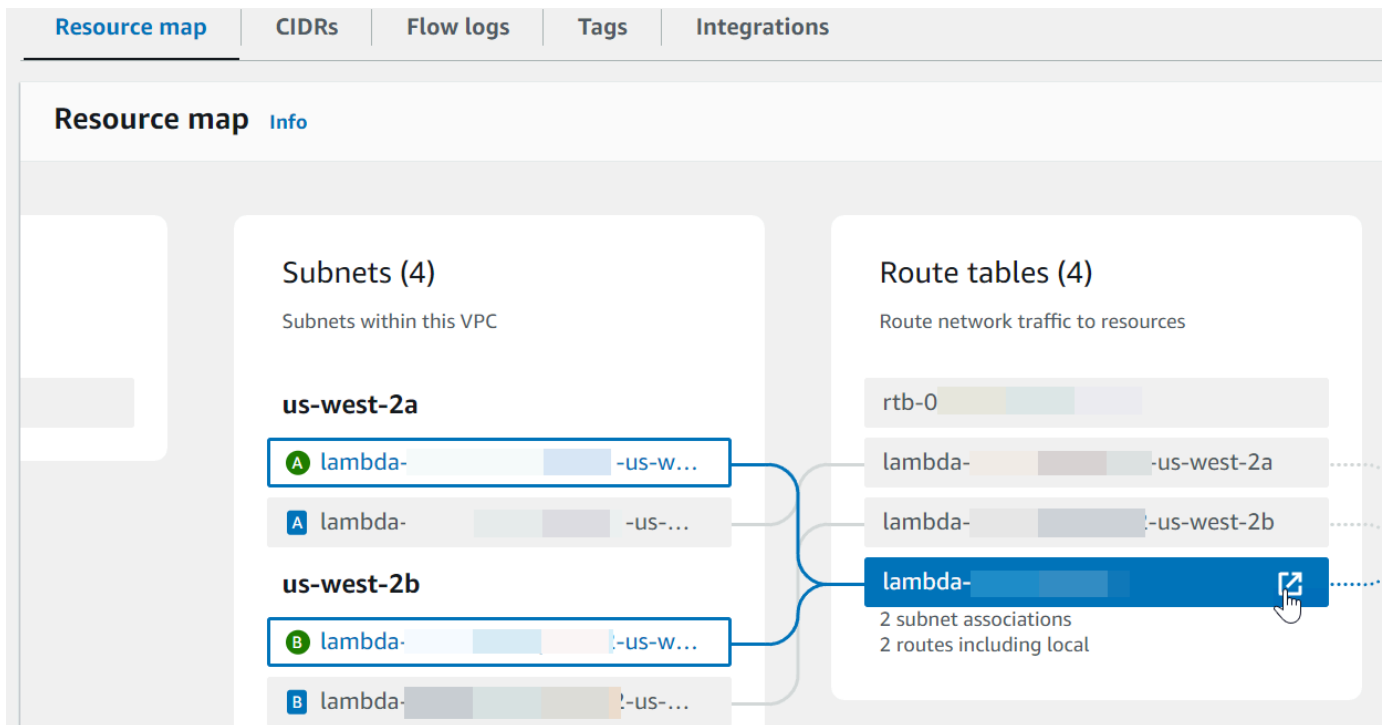

If you already have a VPC but you need to configure public internet access for a Lambda function, follow these steps. This procedure assumes that your VPC has at least two subnets. If you don't have two subnets, see [Create a subnet](#) in the *Amazon VPC User Guide*.

Verify the route table configuration

- Open the Amazon VPC console at <https://console.aws.amazon.com/vpc/>.
- Choose the **VPC ID**.

Your VPCs (3) Info				
<input type="text" value="Search"/>				
<input type="checkbox"/>	Name	VPC ID	State	
<input type="checkbox"/>	-	vpc-2	Available	
<input type="checkbox"/>	lambda-test-vpc	vpc-0	Available	

- Scroll down to the **Resource map** section. Note the route table mappings. Open each route table that is mapped to a subnet.

4. Scroll down to the **Routes** tab. Review the routes to determine if your VPC has both of the following route tables. Each of these requirements must be satisfied by a separate route table.
 - Internet-bound traffic ($0.0.0.0/0$ for IPv4, $:::/0$ for IPv6) is routed to an internet gateway (`igw-xxxxxxxxxx`). This means that the subnet associated with the route table is a public subnet.

Note

If your subnet doesn't have an IPv6 CIDR block, you will only see the IPv4 route ($0.0.0.0/0$).

Example public subnet route table

Routes	Subnet associations	Edge associations	Route propagation	Tags
Routes (4) <div> <input type="text" value="Filter routes"/> </div>				
Destination	Target	Status		
::/0	igw-0	Active		
::/56	local	Active		
0.0.0.0/0	igw-0	Active		
/16	local	Active		

- Internet-bound traffic for IPv4 (0.0.0.0/0) is routed to a NAT gateway (nat-xxxxxxxxxx) that is associated with a public subnet. This means that the subnet is a private subnet that can access the internet through the NAT gateway.

Note

If your subnet has an IPv6 CIDR block, the route table must also route internet-bound IPv6 traffic (:::/0) to an egress-only internet gateway (eigw-xxxxxxxxxx). If your subnet doesn't have an IPv6 CIDR block, you will only see the IPv4 route (0.0.0.0/0).

Example private subnet route table

Routes	Subnet associations	Edge associations	Route propagation	Tags
Routes (4) <input type="text" value="Filter routes"/>				
Destination	Target	Status		
::/0	eigw-0	Active		
::/56	local	Active		
0.0.0.0/0	nat-0	Active		
/16	local	Active		

- Repeat the previous step until you have reviewed each route table associated with a subnet in your VPC and confirmed that you have a route table with an internet gateway and a route table with a NAT gateway.

If you don't have two route tables, one with a route to an internet gateway and one with a route to a NAT gateway, follow these steps to create the missing resources and route table entries.

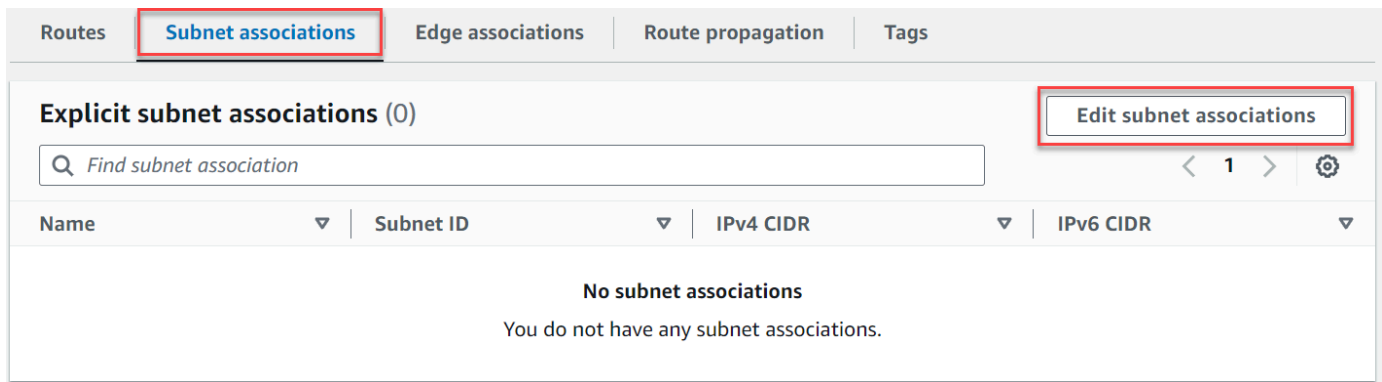

Create a route table

Follow these steps to create a route table and associate it with a subnet.

To create a custom route table using the Amazon VPC console

- Open the Amazon VPC console at <https://console.aws.amazon.com/vpc/>.
- In the navigation pane, choose **Route tables**.
- Choose **Create route table**.
- (Optional) For **Name**, enter a name for your route table.
- For **VPC**, choose your VPC.
- (Optional) To add a tag, choose **Add new tag** and enter the tag key and tag value.
- Choose **Create route table**.

8. On the **Subnet associations** tab, choose **Edit subnet associations**.

9. Select the check box for the subnet to associate with the route table.

10. Choose **Save associations**.

Create an internet gateway

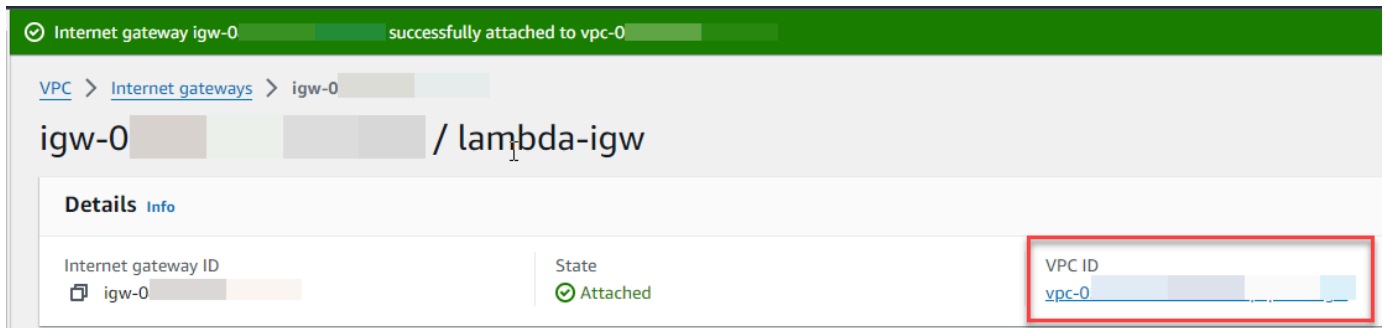

Follow these steps to create an internet gateway, attach it to your VPC, and add it to your public subnet's route table.

To create an internet gateway

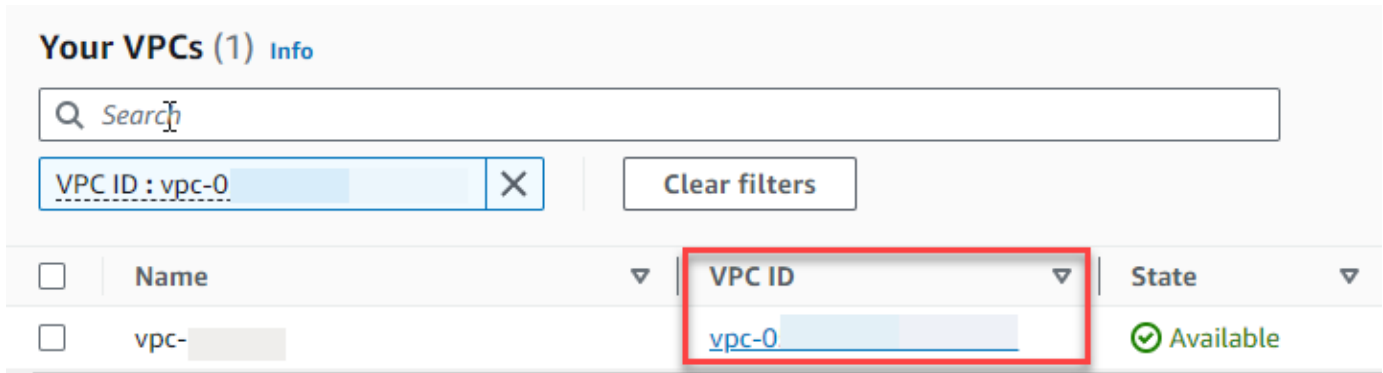

1. Open the Amazon VPC console at <https://console.aws.amazon.com/vpc/>.
2. In the navigation pane, choose **Internet gateways**.
3. Choose **Create internet gateway**.
4. (Optional) Enter a name for your internet gateway.
5. (Optional) To add a tag, choose **Add new tag** and enter the tag key and value.
6. Choose **Create internet gateway**.
7. Choose **Attach to a VPC** from the banner at the top of the screen, select an available VPC, and then choose **Attach internet gateway**.

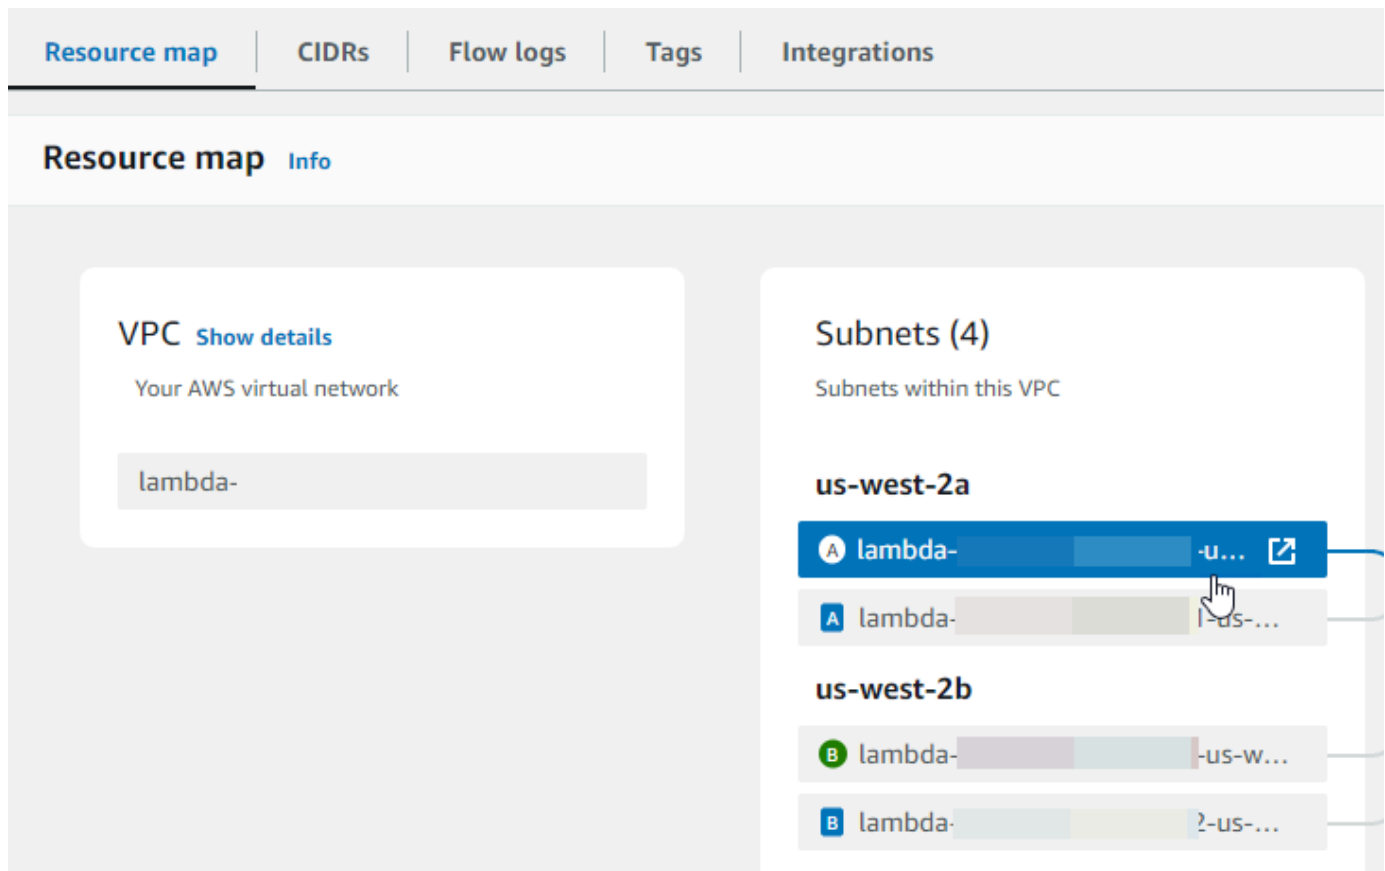

8. Choose the **VPC ID**.

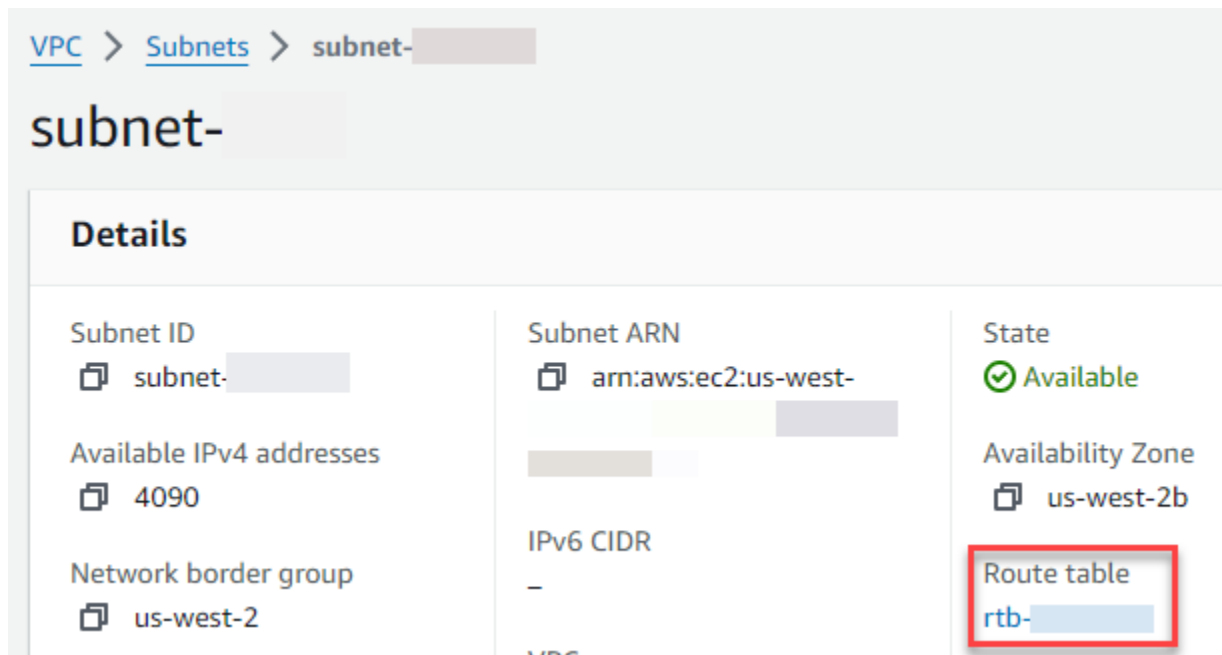

9. Choose the **VPC ID** again to open the VPC details page.

10. Scroll down to the **Resource map** section and then choose a subnet. The subnet details are displayed in a new tab.

11. Choose the link under **Route table**.

12. Choose the **Route table ID** to open the route table details page.

Route tables (1) [Info](#)

Find resources by attribute or tag

Route table ID : rtb-0 X Clear filters

<input type="checkbox"/>	Name	Route table ID
<input type="checkbox"/>	-	rtb-0

13. Under **Routes**, choose **Edit routes**.

Routes | Subnet associations | Edge associations | Route propagation | Tags

Routes (1) Both **Edit routes**

Filter routes

Destination	Target	Status
10.0.0.0/24	local	Active

14. Choose **Add route**, and then enter `0.0.0.0/0` in the **Destination** box.

Edit routes

Destination	Target	Status
10.0.0.0/24	local	Active
0.0.0.0/0		
0.0.0.0/8		
0.0.0.0/16		

15. For **Target**, select **Internet gateway**, and then choose the internet gateway that you created earlier. If your subnet has an IPv6 CIDR block, you must also add a route for `:::/0` to the same internet gateway.

Edit routes

Destination	Target
10.0.0.0/24	local
<input type="text" value="0.0.0.0/0"/>	<input type="text" value="local"/>
<input type="button" value="Add route"/>	<div><div>Carrier Gateway</div><div>Core Network</div><div>Egress Only Internet Gateway</div><div>Gateway Load Balancer Endpoint</div><div>Instance</div><div>Internet Gateway</div></div>

16. Choose **Save changes**.

Create a NAT gateway

Follow these steps to create a NAT gateway, associate it with a public subnet, and then add it to your private subnet's route table.

To create a NAT gateway and associate it with a public subnet

1. In the navigation pane, choose **NAT gateways**.
2. Choose **Create NAT gateway**.
3. (Optional) Enter a name for your NAT gateway.
4. For **Subnet**, select a public subnet in your VPC. (A public subnet is a subnet that has a direct route to an internet gateway in its route table.)

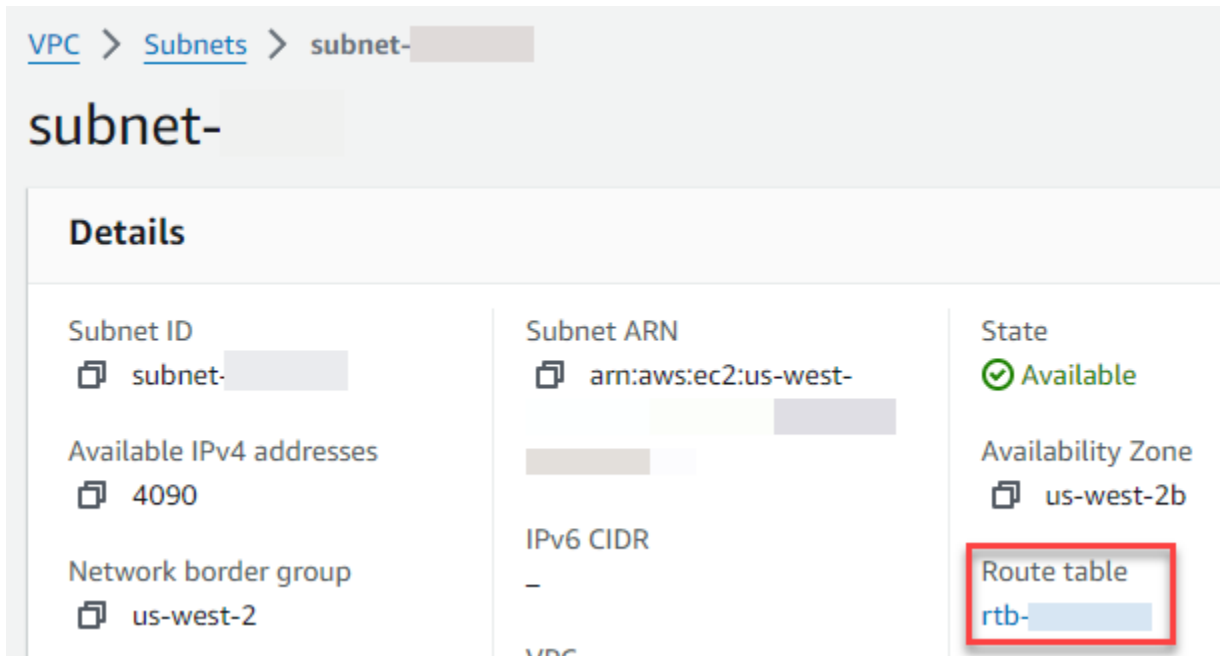

Note

NAT gateways are associated with a public subnet, but the route table entry is in the private subnet.

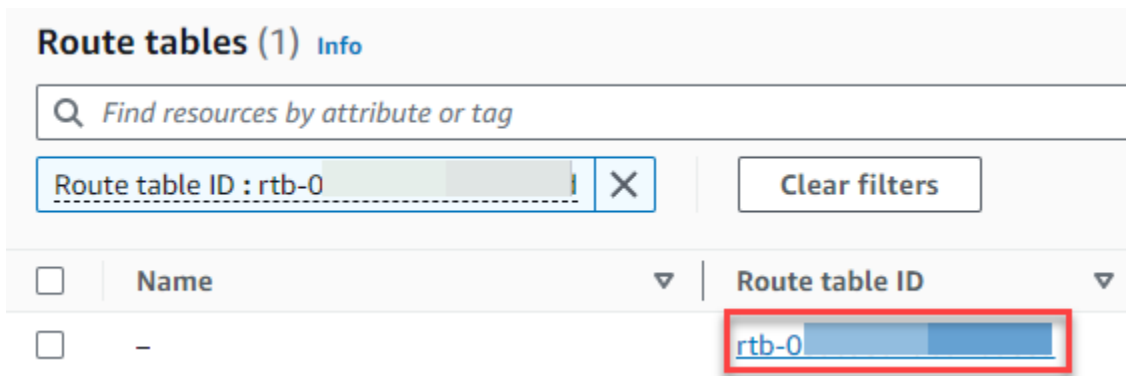

5. For **Elastic IP allocation ID**, select an elastic IP address or choose **Allocate Elastic IP**.
6. Choose **Create NAT gateway**.

To add a route to the NAT gateway in the private subnet's route table

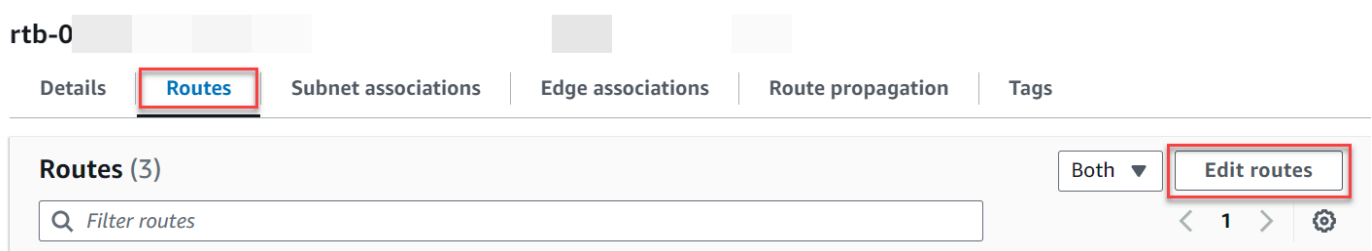

1. In the navigation pane, choose **Subnets**.
2. Select a private subnet in your VPC. (A private subnet is a subnet that doesn't have a route to an internet gateway in its route table.)
3. Choose the link under **Route table**.

4. Choose the **Route table ID** to open the route table details page.

5. Scroll down and choose the **Routes** tab, then choose **Edit routes**

6. Choose **Add route**, and then enter `0.0.0.0/0` in the **Destination** box.

Destination	Target	Status
10.0.0.0/24	local	Active

Search: 0.0.0.0/0

- 0.0.0.0/0
- 0.0.0.0/8
- 0.0.0.0/16

7. For **Target**, select **NAT gateway**, and then choose the NAT gateway that you created earlier.

VPC > Route tables > rtb- > Edit routes

- Instance
- Internet Gateway
- local
- NAT Gateway**
- Network Interface

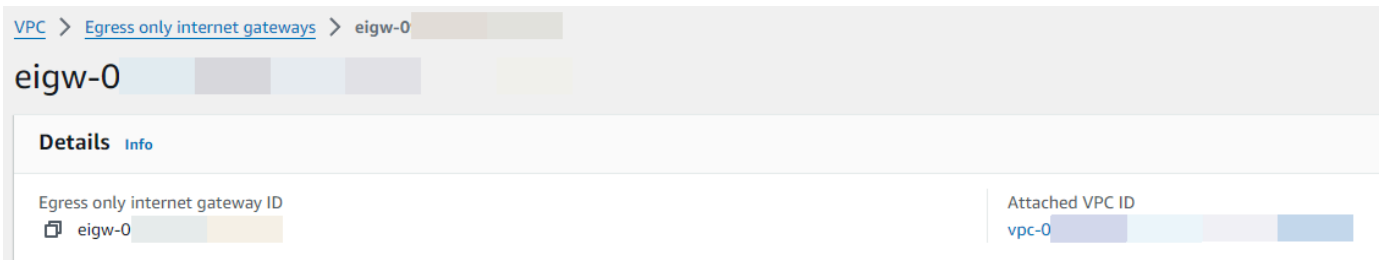

8. Choose **Save changes**.

Create an egress-only internet gateway (IPv6 only)

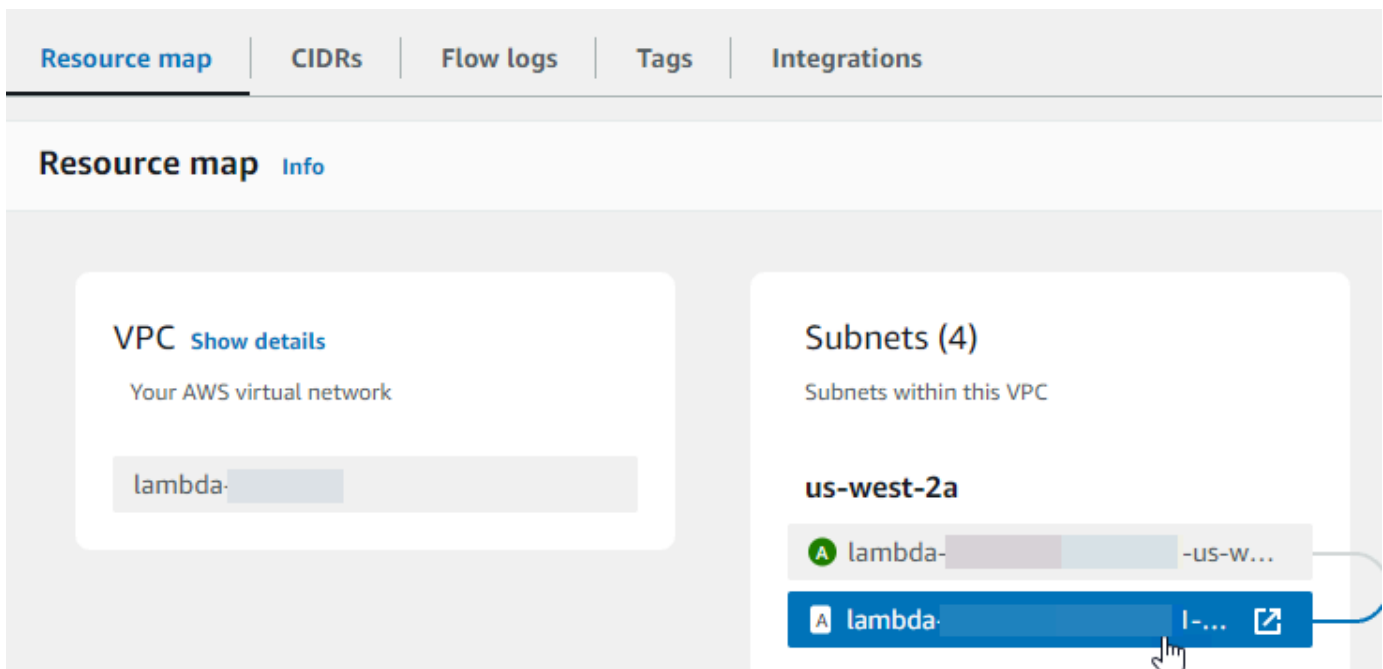

Follow these steps to create an egress-only internet gateway and add it to your private subnet's route table.

To create an egress-only internet gateway

1. In the navigation pane, choose **Egress-only internet gateways**.
2. Choose **Create egress only internet gateway**.
3. (Optional) Enter a name.
4. Select the VPC in which to create the egress-only internet gateway.
5. Choose **Create egress only internet gateway**.
6. Choose the link under **Attached VPC ID**.

7. Choose the link under **VPC ID** to open the VPC details page.
8. Scroll down to the **Resource map** section and then choose a private subnet. (A private subnet is a subnet that doesn't have a route to an internet gateway in its route table.) The subnet details are displayed in a new tab.

9. Choose the link under **Route table**.

subnet-0 -subnet-private1-us-west-2a

Configure the Lambda function

To configure a VPC when you create a function

- Open the [Functions page](#) of the Lambda console.
- Choose **Create function**.
- Under **Basic information**, for **Function name**, enter a name for your function.
- Expand **Advanced settings**.
- Select **Enable VPC**, and then choose a VPC.
- (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
- For **Subnets**, select all private subnets. The private subnets can access the internet through the NAT gateway. Connecting a function to a public subnet doesn't give it internet access.

Note

If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

- For **Security groups**, select a security group that allows outbound traffic.
- Choose **Create function**.

Lambda automatically creates an execution role with the [AWSLambdaVPCAccessExecutionRole](#) AWS managed policy. The permissions in this policy are required only to create elastic network interfaces for the VPC configuration, not to invoke your function. To apply least-privilege permissions, you can remove the **AWSLambdaVPCAccessExecutionRole** policy from your execution role after you create the function and VPC configuration. For more information, see [Required IAM permissions](#).

To configure a VPC for an existing function

To add a VPC configuration to an existing function, the function's execution role must have [permission to create and manage elastic network interfaces](#). The [AWSLambdaVPCAccessExecutionRole](#) AWS managed policy includes the required permissions. To apply least-privilege permissions, you can remove the **AWSLambdaVPCAccessExecutionRole** policy from your execution role after you create the VPC configuration.

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose the **Configuration** tab, and then choose **VPC**.
4. Under **VPC**, choose **Edit**.
5. Select the VPC.
6. (Optional) To allow [outbound IPv6 traffic](#), select **Allow IPv6 traffic for dual-stack subnets**.
7. For **Subnets**, select all private subnets. The private subnets can access the internet through the NAT gateway. Connecting a function to a public subnet doesn't give it internet access.

Note

If you selected **Allow IPv6 traffic for dual-stack subnets**, all selected subnets must have an IPv4 CIDR block and an IPv6 CIDR block.

8. For **Security groups**, select a security group that allows outbound traffic.
9. Choose **Save**.

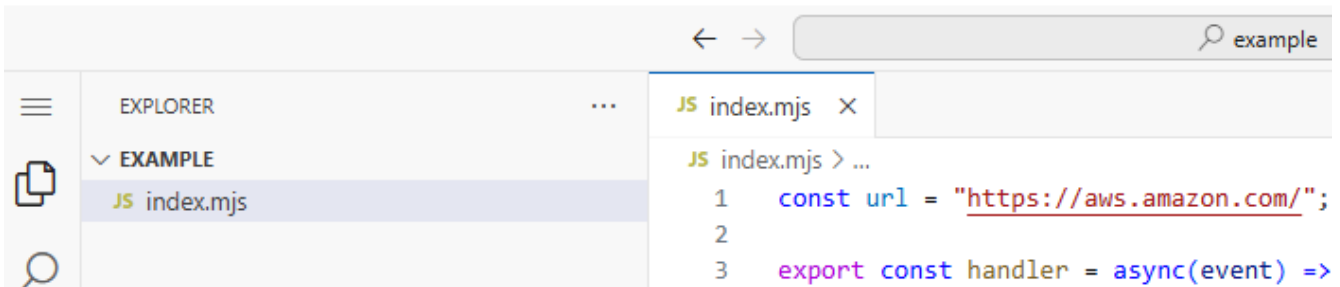

Test the function

Use the following sample code to confirm that your VPC-connected function can reach the public internet. If successful, the code returns a 200 status code. If unsuccessful, the function times out.

Node.js

1. In the **Code source** pane on the Lambda console, paste the following code into the **index.mjs** file. The function makes an HTTP GET request to a public endpoint and returns the HTTP response code to test if the function has access to the public internet.

Code source [Info](#)

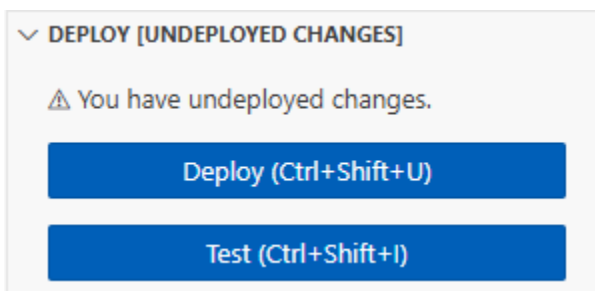

Example — HTTP request with async/await

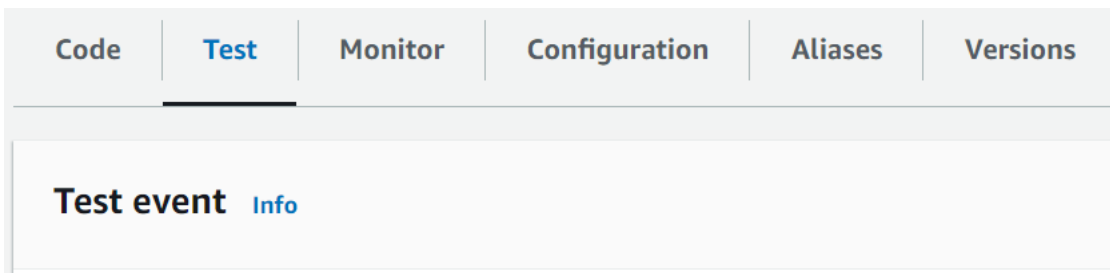

```
const url = "https://aws.amazon.com/";

export const handler = async(event) => {
  try {
    const res = await fetch(url);
    console.info("status", res.status);
    return res.status;
  }
  catch (e) {
    console.error(e);
    return 500;
  }
};
```

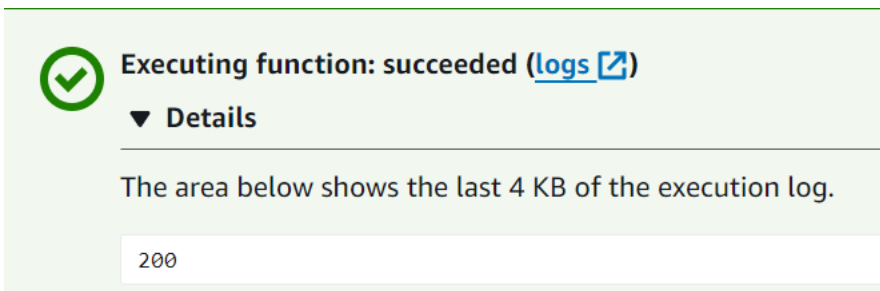

2. In the **DEPLOY** section, choose **Deploy** to update your function's code:

3. Choose the **Test** tab.

4. Choose **Test**.
5. The function returns a 200 status code. This means that the function has outbound internet access.

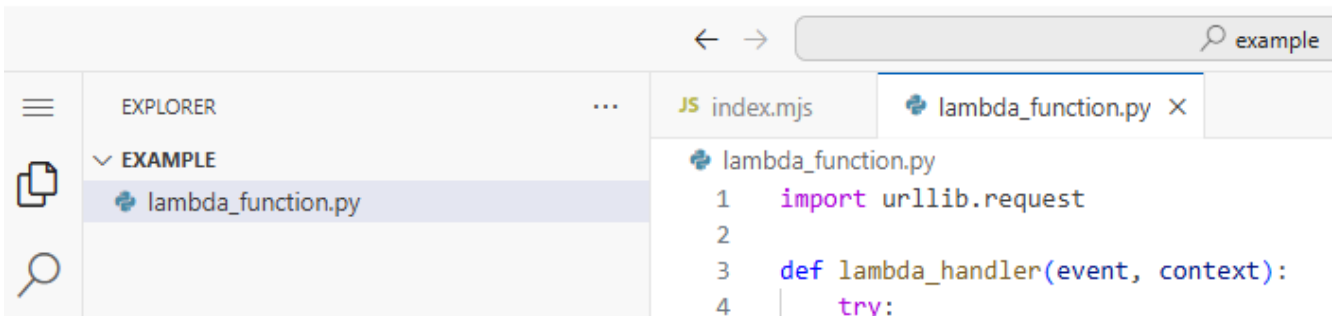

If the function can't reach the public internet, you get an error message like this:

```
{
  "errorMessage": "2024-04-11T17:22:20.857Z abe12jlc-640a-8157-0249-9be825c2y110
Task timed out after 3.01 seconds"
}
```

Python

1. In the **Code source** pane on the Lambda console, paste the following code into the **lambda_function.py** file. The function makes an HTTP GET request to a public endpoint and returns the HTTP response code to test if the function has access to the public internet.

Code source [Info](#)

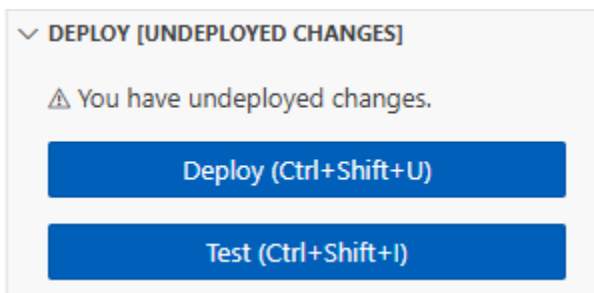

```

import urllib.request

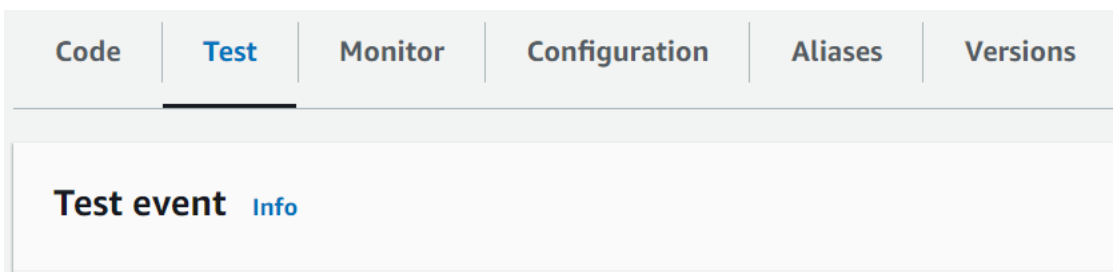

def lambda_handler(event, context):
    try:
        response = urllib.request.urlopen('https://aws.amazon.com')
        status_code = response.getcode()
        print('Response Code:', status_code)
        return status_code
    except Exception as e:
        print('Error:', e)
        raise e

```

- In the **DEPLOY** section, choose **Deploy** to update your function's code:

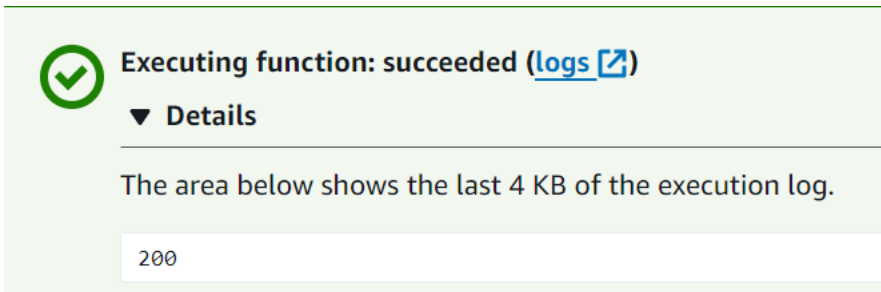

- Choose the **Test** tab.

- Choose **Test**.

5. The function returns a 200 status code. This means that the function has outbound internet access.

If the function can't reach the public internet, you get an error message like this:

```
{
  "errorMessage": "2024-04-11T17:22:20.857Z abe12jlc-640a-8157-0249-9be825c2y110
Task timed out after 3.01 seconds"
}
```

Connecting inbound interface VPC endpoints for Lambda

If you use Amazon Virtual Private Cloud (Amazon VPC) to host your AWS resources, you can establish a connection between your VPC and Lambda. You can use this connection to invoke your Lambda function without crossing the public internet.

To establish a private connection between your VPC and Lambda, create an [interface VPC endpoint](#). Interface endpoints are powered by [AWS PrivateLink](#), which enables you to privately access Lambda APIs without an internet gateway, NAT device, VPN connection, or AWS Direct Connect connection. Instances in your VPC don't need public IP addresses to communicate with Lambda APIs. Traffic between your VPC and Lambda does not leave the AWS network.

Each interface endpoint is represented by one or more [elastic network interfaces](#) in your subnets. A network interface provides a private IP address that serves as an entry point for traffic to Lambda.

Sections

- [Considerations for Lambda interface endpoints](#)
- [Creating an interface endpoint for Lambda](#)
- [Creating an interface endpoint policy for Lambda](#)

Considerations for Lambda interface endpoints

Before you set up an interface endpoint for Lambda, be sure to review [Interface endpoint properties and limitations](#) in the *Amazon VPC User Guide*.

You can call any of the Lambda API operations from your VPC. For example, you can invoke the Lambda function by calling the Invoke API from within your VPC. For the full list of Lambda APIs, see [Actions](#) in the Lambda API reference.

use1-az3 is a limited capacity Region for Lambda VPC functions. You shouldn't use subnets in this availability zone with your Lambda functions because this can result in reduced zonal redundancy in the event of an outage.

Keep-alive for persistent connections

Lambda purges idle connections over time, so you must use a keep-alive directive to maintain persistent connections. Attempting to reuse an idle connection when invoking a function results in a connection error. To maintain your persistent connection, use the keep-alive directive associated

with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#) in the *AWS SDK for JavaScript Developer Guide*.

Billing Considerations

There is no additional cost to access a Lambda function through an interface endpoint. For more Lambda pricing information, see [AWS Lambda Pricing](#).

Standard pricing for AWS PrivateLink applies to interface endpoints for Lambda. Your AWS account is billed for every hour an interface endpoint is provisioned in each Availability Zone and for data processed through the interface endpoint. For more interface endpoint pricing information, see [AWS PrivateLink pricing](#).

VPC Peering Considerations

You can connect other VPCs to the VPC with interface endpoints using [VPC peering](#). VPC peering is a networking connection between two VPCs. You can establish a VPC peering connection between your own two VPCs, or with a VPC in another AWS account. The VPCs can also be in two different AWS Regions.

Traffic between peered VPCs stays on the AWS network and does not traverse the public internet. Once VPCs are peered, resources like Amazon Elastic Compute Cloud (Amazon EC2) instances, Amazon Relational Database Service (Amazon RDS) instances, or VPC-enabled Lambda functions in both VPCs can access the Lambda API through interface endpoints created in the one of the VPCs.

Creating an interface endpoint for Lambda

You can create an interface endpoint for Lambda using either the Amazon VPC console or the AWS Command Line Interface (AWS CLI). For more information, see [Creating an interface endpoint](#) in the *Amazon VPC User Guide*.

To create an interface endpoint for Lambda (console)

1. Open the [Endpoints page](#) of the Amazon VPC console.
2. Choose **Create Endpoint**.
3. For **Service category**, verify that **AWS services** is selected.
4. For **Service Name**, choose **com.amazonaws.*region*.lambda**. Verify that the **Type** is **Interface**.
5. Choose a VPC and subnets.

6. To enable private DNS for the interface endpoint, select the **Enable DNS Name** check box. We recommend that you enable private DNS names for your VPC endpoints for AWS services. This ensures that requests that use the public service endpoints, such as requests made through an AWS SDK, resolve to your VPC endpoint.
7. For **Security group**, choose one or more security groups.
8. Choose **Create endpoint**.

To use the private DNS option, you must set the `enableDnsHostnames` and `enableDnsSupport` attributes of your VPC. For more information, see [Viewing and updating DNS support for your VPC](#) in the *Amazon VPC User Guide*. If you enable private DNS for the interface endpoint, you can make API requests to Lambda using its default DNS name for the Region, for example, `lambda.us-east-1.amazonaws.com`. For more service endpoints, see [Service endpoints and quotas](#) in the *AWS General Reference*.

For more information, see [Accessing a service through an interface endpoint](#) in the *Amazon VPC User Guide*.

For information about creating and configuring an endpoint using CloudFormation, see the [AWS::EC2::VPCEndpoint](#) resource in the *AWS CloudFormation User Guide*.

To create an interface endpoint for Lambda (AWS CLI)

Use the [create-vpc-endpoint](#) command and specify the VPC ID, VPC endpoint type (interface), service name, subnets that will use the endpoint, and security groups to associate with the endpoint's network interfaces. For example:

```
aws ec2 create-vpc-endpoint
  --vpc-id vpc-ec43eb89
  --vpc-endpoint-type Interface
  --service-name com.amazonaws.us-east-1.lambda
  --subnet-id subnet-abababab
  --security-group-id sg-1a2b3c4d
```

Creating an interface endpoint policy for Lambda

To control who can use your interface endpoint and which Lambda functions the user can access, you can attach an endpoint policy to your endpoint. The policy specifies the following information:

- The principal that can perform actions.

- The actions that the principal can perform.
- The resources on which the principal can perform actions.

For more information, see [Controlling access to services with VPC endpoints](#) in the *Amazon VPC User Guide*.

Example: Interface endpoint policy for Lambda actions

The following is an example of an endpoint policy for Lambda. When attached to an endpoint, this policy allows user `MyUser` to invoke the function `my-function`.

Note

You need to include both the qualified and the unqualified function ARN in the resource.

```
{
  "Statement": [
    {
      "Principal": {
        "AWS": "arn:aws:iam::111122223333:user/MyUser"
      },
      "Effect": "Allow",
      "Action": [
        "lambda:InvokeFunction"
      ],
      "Resource": [
        "arn:aws:lambda:us-east-2:123456789012:function:my-function",
        "arn:aws:lambda:us-east-2:123456789012:function:my-function:*"
      ]
    }
  ]
}
```

Configuring file system access for Lambda functions

You can configure a function to mount an Amazon Elastic File System (Amazon EFS) file system to a local directory. With Amazon EFS, your function code can access and modify shared resources safely and at high concurrency.

Supported Regions

Amazon EFS for Lambda is available in all [commercial Regions](#) except Asia Pacific (New Zealand), Asia Pacific (Taipei), Asia Pacific (Malaysia), Mexico (Central), Asia Pacific (Thailand), and Canada West (Calgary).

Sections

- [Execution role and user permissions](#)
- [Configuring a file system and access point](#)
- [Connecting to a file system \(console\)](#)

Execution role and user permissions

If the file system doesn't have a user-configured AWS Identity and Access Management (IAM) policy, EFS uses a default policy that grants full access to any client that can connect to the file system using a file system mount target. If the file system has a user-configured IAM policy, your function's execution role must have the correct `elasticfilesystem` permissions.

Execution role permissions

- `elasticfilesystem:ClientMount`
- `elasticfilesystem:ClientWrite` (not required for read-only connections)

These permissions are included in the **AmazonElasticFileSystemClientReadWriteAccess** managed policy. Additionally, your execution role must have the [permissions required to connect to the file system's VPC](#).

When you configure a file system, Lambda uses your permissions to verify mount targets. To configure a function to connect to a file system, your user needs the following permissions:

User permissions

- `elasticfilesystem:DescribeMountTargets`

Configuring a file system and access point

Create a file system in Amazon EFS with a mount target in every Availability Zone that your function connects to. For performance and resilience, use at least two Availability Zones. For example, in a simple configuration you could have a VPC with two private subnets in separate Availability Zones. The function connects to both subnets and a mount target is available in each. Ensure that NFS traffic (port 2049) is allowed by the security groups used by the function and mount targets.

Note

When you create a file system, you choose a performance mode that can't be changed later. **General purpose** mode has lower latency, and **Max I/O** mode supports a higher maximum throughput and IOPS. For help choosing, see [Amazon EFS performance](#) in the *Amazon Elastic File System User Guide*.

An access point connects each instance of the function to the right mount target for the Availability Zone it connects to. For best performance, create an access point with a non-root path, and limit the number of files that you create in each directory. The following example creates a directory named `my-function` on the file system and sets the owner ID to 1001 with standard directory permissions (755).

Example access point configuration

- **Name** – `files`
- **User ID** – 1001
- **Group ID** – 1001
- **Path** – `/my-function`
- **Permissions** – 755
- **Owner user ID** – 1001
- **Group user ID** – 1001

When a function uses the access point, it is given user ID 1001 and has full access to the directory.

For more information, see the following topics in the *Amazon Elastic File System User Guide*:

- [Creating resources for Amazon EFS](#)
- [Working with users, groups, and permissions](#)

Connecting to a file system (console)

A function connects to a file system over the local network in a VPC. The subnets that your function connects to can be the same subnets that contain mount points for your file system, or subnets in the same Availability Zone that can route NFS traffic (port 2049) to the file system.

Note

If your function is not already connected to a VPC, see [Giving Lambda functions access to resources in an Amazon VPC](#).

To configure file system access

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **File systems**.
4. Under **File system**, choose **Add file system**.
5. Configure the following properties:
 - **EFS file system** – The access point for a file system in the same VPC.
 - **Local mount path** – The location where the file system is mounted on the Lambda function, starting with `/mnt/`.

Pricing

Amazon EFS charges for storage and throughput, with rates that vary by storage class. For details, see [Amazon EFS pricing](#).

Lambda charges for data transfer between VPCs. This only applies if your function's VPC is peered to another VPC with a file system. The rates are the same as for Amazon EC2 data transfer between VPCs in the same Region. For details, see [Lambda pricing](#).

Create an alias for a Lambda function

You can create aliases for your Lambda function. A Lambda alias is a pointer to a function version that you can update. The function's users can access the function version using the alias Amazon Resource Name (ARN). When you deploy a new version, you can update the alias to use the new version, or split traffic between two versions.

Console

To create an alias using the console

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Aliases** and then choose **Create alias**.
4. On the **Create alias** page, do the following:
 - a. Enter a **Name** for the alias.
 - b. (Optional) Enter a **Description** for the alias.
 - c. For **Version**, choose a function version that you want the alias to point to.
 - d. (Optional) To configure routing on the alias, expand **Weighted alias**. For more information, see [Implement Lambda canary deployments using a weighted alias](#).
 - e. Choose **Save**.

AWS CLI

To create an alias using the AWS Command Line Interface (AWS CLI), use the [create-alias](#) command.

```
aws lambda create-alias \  
  --function-name my-function \  
  --name alias-name \  
  --function-version version-number \  
  --description " "
```

To change an alias to point a new version of the function, use the [update-alias](#) command.

```
aws lambda update-alias \  
  --function-name my-function \  
  --alias-name alias-name \  
  --function-version version-number
```

```
--name alias-name \  
--function-version version-number
```

To delete an alias, use the [delete-alias](#) command.

```
aws lambda delete-alias \  
  --function-name my-function \  
  --name alias-name
```

The AWS CLI commands in the preceding steps correspond to the following Lambda API operations:

- [CreateAlias](#)
- [UpdateAlias](#)
- [DeleteAlias](#)

Using Lambda aliases in event sources and permissions policies

Each alias has a unique ARN. An alias can point only to a function version, not to another alias. You can update an alias to point to a new version of the function.

Event sources such as Amazon Simple Storage Service (Amazon S3) invoke your Lambda function. These event sources maintain a mapping that identifies the function to invoke when events occur. If you specify a Lambda function alias in the mapping configuration, you don't need to update the mapping when the function version changes. For more information, see [How Lambda processes records from stream and queue-based event sources](#).

In a resource policy, you can grant permissions for event sources to use your Lambda function. If you specify an alias ARN in the policy, you don't need to update the policy when the function version changes.

Resource policies

You can use a [resource-based policy](#) to give a service, resource, or account access to your function. The scope of that permission depends on whether you apply it to an alias, a version, or the entire function. For example, if you use an alias name (such as `helloworld:PROD`), the permission allows you to invoke the `helloworld` function using the alias ARN (`helloworld:PROD`).

If you attempt to invoke the function without an alias or a specific version, then you get a permission error. This permission error still occurs even if you attempt to directly invoke the function version associated with the alias.

For example, the following AWS CLI command grants Amazon S3 permissions to invoke the `PROD` alias of the `helloworld` function when Amazon S3 is acting on behalf of `amzn-s3-demo-bucket`.

```
aws lambda add-permission \  
  --function-name helloworld \  
  --qualifier PROD \  
  --statement-id 1 \  
  --principal s3.amazonaws.com \  
  --action lambda:InvokeFunction \  
  --source-arn arn:aws:s3:::amzn-s3-demo-bucket \  
  --source-account 123456789012
```

For more information about using resource names in policies, see [Fine-tuning the Resources and Conditions sections of policies](#).

Implement Lambda canary deployments using a weighted alias

You can use a weighted alias to split traffic between two different [versions](#) of the same function. With this approach, you can test new versions of your functions with a small percentage of traffic and quickly roll back if necessary. This is known as a [canary deployment](#). Canary deployments differ from blue/green deployments by exposing the new version to only a portion of requests rather than switching all traffic at once.

You can point an alias to a maximum of two Lambda function versions. The versions must meet the following criteria:

- Both versions must have the same [execution role](#).
- Both versions must have the same [dead-letter queue](#) configuration, or no dead-letter queue configuration.
- Both versions must be published. The alias cannot point to \$LATEST.

Note

Lambda uses a simple probabilistic model to distribute the traffic between the two function versions. At low traffic levels, you might see a high variance between the configured and actual percentage of traffic on each version. If your function uses provisioned concurrency, you can avoid [spillover invocations](#) by configuring a higher number of provisioned concurrency instances during the time that alias routing is active.

Create a weighted alias

Console

To configure routing on an alias using the console

Note

Verify that the function has at least two published versions. To create additional versions, follow the instructions in [Creating function versions](#).

1. Open the [Functions page](#) of the Lambda console.

2. Choose a function.
3. Choose **Aliases** and then choose **Create alias**.
4. On the **Create alias** page, do the following:
 - a. Enter a **Name** for the alias.
 - b. (Optional) Enter a **Description** for the alias.
 - c. For **Version**, choose the first function version that you want the alias to point to.
 - d. Expand **Weighted alias**.
 - e. For **Additional version**, choose the second function version that you want the alias to point to.
 - f. For **Weight (%)**, enter a weight value for the function. *Weight* is the percentage of traffic that is assigned to that version when the alias is invoked. The first version receives the residual weight. For example, if you specify 10 percent to **Additional version**, the first version is assigned 90 percent automatically.
 - g. Choose **Save**.

AWS CLI

Use the [create-alias](#) and [update-alias](#) AWS CLI commands to configure the traffic weights between two function versions. When you create or update the alias, you specify the traffic weight in the `routing-config` parameter.

The following example creates a Lambda function alias named **routing-alias** that points to version 1 of the function. Version 2 of the function receives 3 percent of the traffic. The remaining 97 percent of traffic is routed to version 1.

```
aws lambda create-alias \  
  --name routing-alias \  
  --function-name my-function \  
  --function-version 1 \  
  --routing-config AdditionalVersionWeights={"2":0.03}
```

Use the `update-alias` command to increase the percentage of incoming traffic to version 2. In the following example, you increase the traffic to 5 percent.

```
aws lambda update-alias \  
  --name routing-alias \  
  --routing-config AdditionalVersionWeights={"2":0.05}
```

```
--function-name my-function \  
--routing-config AdditionalVersionWeights={"2"]=0.05}
```

To route all traffic to version 2, use the `update-alias` command to change the `function-version` property to point the alias to version 2. The command also resets the routing configuration.

```
aws lambda update-alias \  
  --name routing-alias \  
  --function-name my-function \  
  --function-version 2 \  
  --routing-config AdditionalVersionWeights={}
```

The AWS CLI commands in the preceding steps correspond to the following Lambda API operations:

- [CreateAlias](#)
- [UpdateAlias](#)

Determining which version was invoked

When you configure traffic weights between two function versions, there are two ways to determine the Lambda function version that has been invoked:

- **CloudWatch Logs** – Lambda automatically emits a START log entry that contains the invoked version ID for every function invocation. Example:

```
START RequestId: 1dh194d3759ed-4v8b-a7b4-1e541f60235f Version: 2
```

For alias invocations, Lambda uses the `ExecutedVersion` dimension to filter the metric data by the invoked version. For more information, see [Viewing metrics for Lambda functions](#).

- **Response payload (synchronous invocations)** – Responses to synchronous function invocations include an `x-amz-executed-version` header to indicate which function version has been invoked.

Create a rolling deployment with weighted aliases

Use AWS CodeDeploy and AWS Serverless Application Model (AWS SAM) to create a rolling deployment that automatically detects changes to your function code, deploys a new version of

your function, and gradually increase the amount of traffic flowing to the new version. The amount of traffic and rate of increase are parameters that you can configure.

In a rolling deployment, AWS SAM performs these tasks:

- Configures your Lambda function and creates an alias. The weighted alias routing configuration is the underlying capability that implements the rolling deployment.
- Creates a CodeDeploy application and deployment group. The deployment group manages the rolling deployment and the rollback, if needed.
- Detects when you create a new version of your Lambda function.
- Triggers CodeDeploy to start the deployment of the new version.

Example AWS SAM template

The following example shows an [AWS SAM template](#) for a simple rolling deployment.

```
AWSTemplateFormatVersion : '2010-09-09'
Transform: AWS::Serverless-2016-10-31
Description: A sample SAM template for deploying Lambda functions

Resources:
# Details about the myDateTimeFunction Lambda function
  myDateTimeFunction:
    Type: AWS::Serverless::Function
    Properties:
      Handler: myDateTimeFunction.handler
      Runtime: nodejs24.x
# Creates an alias named "live" for the function, and automatically publishes when you
  update the function.
    AutoPublishAlias: live
    DeploymentPreference:
# Specifies the deployment configuration
      Type: Linear10PercentEvery2Minutes
```

This template defines a Lambda function named `myDateTimeFunction` with the following properties.

AutoPublishAlias

The `AutoPublishAlias` property creates an alias named `live`. In addition, the AWS SAM framework automatically detects when you save new code for the function. The framework then publishes a new function version and updates the `live` alias to point to the new version.

DeploymentPreference

The `DeploymentPreference` property determines the rate at which the CodeDeploy application shifts traffic from the original version of the Lambda function to the new version. The value `Linear10PercentEvery2Minutes` shifts an additional ten percent of the traffic to the new version every two minutes.

For a list of the predefined deployment configurations, see [Deployment configurations](#).

For more information on how to create rolling deployments with CodeDeploy and AWS SAM, see the following:

- [Tutorial: Deploy an updated Lambda function with CodeDeploy and the AWS Serverless Application Model](#)
- [Deploying serverless applications gradually with AWS SAM](#)

Manage Lambda function versions

You can use versions to manage the deployment of your functions. For example, you can publish a new version of a function for beta testing without affecting users of the stable production version. Lambda creates a new version of your function each time that you publish the function. The new version is a copy of the unpublished version of the function. The unpublished version is named `$LATEST`.

Importantly, any time you deploy your function code, you overwrite the current code in `$LATEST`. To save the current iteration of `$LATEST`, create a new function version. If `$LATEST` is identical to a previously published version, you won't be able to create a new version until you deploy changes to `$LATEST`. These changes can include updating the code, or modifying the function configuration settings.

After you publish a function version, its code, runtime, architecture, memory, layers, and most other configuration settings are immutable. This means that you can't change these settings without publishing a new version from `$LATEST`. You can configure the following items for a published function version:

- [Triggers](#)
- [Destinations](#)
- [Provisioned concurrency](#)
- [Asynchronous invocation](#)
- [Database connections and proxies](#)

Note

When using [runtime management controls](#) with **Auto** mode, the runtime version used by the function version is updated automatically. When using **Function update** or **Manual** mode, the runtime version is not updated. For more information, see [the section called "Runtime version updates"](#).

Sections

- [Creating function versions](#)
- [Using versions](#)

- [Granting permissions](#)

Creating function versions

You can change the function code and settings only on the unpublished version of a function. When you publish a version, Lambda locks the code and most of the settings to maintain a consistent experience for users of that version.

You can create a function version using the Lambda console.

To create a new function version

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function and then choose the **Versions** tab.
3. On the versions configuration page, choose **Publish new version**.
4. (Optional) Enter a version description.
5. Choose **Publish**.

Alternatively, you can publish a version of a function using the [PublishVersion](#) API operation.

The following AWS CLI command publishes a new version of a function. The response returns configuration information about the new version, including the version number and the function ARN with the version suffix.

```
aws lambda publish-version --function-name my-function
```

You should see the following output:

```
{
  "FunctionName": "my-function",
  "FunctionArn": "arn:aws:lambda:us-east-2:123456789012:function:my-function:1",
  "Version": "1",
  "Role": "arn:aws:iam::123456789012:role/lambda-role",
  "Handler": "function.handler",
  "Runtime": "nodejs24.x",
  ...
}
```

Note

Lambda assigns monotonically increasing sequence numbers for versioning. Lambda never reuses version numbers, even after you delete and recreate a function.

Using versions

You can reference your Lambda function using either a qualified ARN or an unqualified ARN.

- **Qualified ARN** – The function ARN with a version suffix. The following example refers to version 42 of the helloworld function.

```
arn:aws:lambda:aws-region:acct-id:function:helloworld:42
```

- **Unqualified ARN** – The function ARN without a version suffix.

```
arn:aws:lambda:aws-region:acct-id:function:helloworld
```

You can use a qualified or an unqualified ARN in all relevant API operations. However, you can't use an unqualified ARN to create an alias.

If you decide not to publish function versions, you can invoke the function using either the qualified or unqualified ARN in your [event source mapping](#). When you invoke a function using an unqualified ARN, Lambda implicitly invokes \$LATEST.

The qualified ARN for each Lambda function version is unique. After you publish a version, you can't change the ARN or the function code.

Lambda publishes a new function version only if the code has never been published, or if the code has changed from the last published version. If there is no change, the function version remains at the last published version.

When you publish a version, Lambda creates an immutable snapshot of your function's code and configuration. Not all configuration changes trigger the publication of a new version. The following configuration changes qualify a function for version publication:

- Function code
- Environment variables

- Runtime
- Handler
- Layers
- Memory size
- Timeout
- VPC configuration
- Dead Letter Queue (DLQ) configuration
- IAM role
- Description
- Architecture (x86_64 or arm64)
- Ephemeral storage size
- Package type
- Logging configuration
- File system configuration
- SnapStart
- Tracing configuration

Operational settings such as [reserved concurrency](#) don't trigger the publication of a new version when changed.

Granting permissions

You can use a [resource-based policy](#) or an [identity-based policy](#) to grant access to your function. The scope of the permission depends on whether you apply the policy to a function or to one version of a function. For more information about function resource names in policies, see [Fine-tuning the Resources and Conditions sections of policies](#).

You can simplify the management of event sources and AWS Identity and Access Management (IAM) policies by using function aliases. For more information, see [Create an alias for a Lambda function](#).

Using tags on Lambda functions

You can tag functions to organize and manage your resources. Tags are free-form key-value pairs associated with your resources that are supported across AWS services. For more information about use cases for tags, see [Common tagging strategies](#) in the *Tagging AWS Resources and Tag Editor Guide*.

Tags apply at the function level, not to versions or aliases. Tags are not part of the version-specific configuration that AWS Lambda creates a snapshot of when you publish a version. You can use the Lambda API to view and update tags. You can also view and update tags while managing a specific function in the Lambda console.

Sections

- [Permissions required for working with tags](#)
- [Using tags with the Lambda console](#)
- [Using tags with the AWS CLI](#)

Permissions required for working with tags

To allow an AWS Identity and Access Management (IAM) identity (user, group, or role) to read or set tags on a resource, grant it the corresponding permissions:

- **lambda:ListTags**—When a resource has tags, grant this permission to anyone who needs to call `ListTags` on it. For tagged functions, this permission is also necessary for `GetFunction`.
- **lambda:TagResource**—Grant this permission to anyone who needs to call `TagResource` or perform a tag on create.

Optionally, consider granting the **lambda:UntagResource** permission as well to allow `UntagResource` calls to the resource.

For more information, see [Identity-based IAM policies for Lambda](#).

Using tags with the Lambda console

You can use the Lambda console to create functions that have tags, add tags to existing functions, and filter functions by tags that you add.

To add tags when you create a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Choose **Author from scratch** or **Container image**.
4. Under **Basic information**, set up your function. For more information about configuring functions, see [Configuring functions](#).
5. Expand **Advanced settings**, and then select **Enable tags**.
6. Choose **Add new tag**, and then enter a **Key** and an optional **Value**. To add more tags, repeat this step.
7. Choose **Create function**.

To add tags to an existing function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of a function.
3. Choose **Configuration**, and then choose **Tags**.
4. Under **Tags**, choose **Manage tags**.
5. Choose **Add new tag**, and then enter a **Key** and an optional **Value**. To add more tags, repeat this step.
6. Choose **Save**.

To filter functions with tags

1. Open the [Functions page](#) of the Lambda console.
2. Choose the search box to see a list of function properties and tag keys.
3. Choose a tag key to see a list of values that are in use in the current AWS Region.
4. Select **Use: "tag-name"** to see all functions tagged with this key, or choose an **Operator** to further filter by value.
5. Select your tag value to filter by a combination of tag key and value.

The search bar also supports searching for tag keys. Enter tag to see only a list of tag keys, or enter the name of a key to find it in the list.

Using tags with the AWS CLI

You can add and remove tags on existing Lambda resources, including functions, with the Lambda API. You can also add tags when creating a function, which allows you to keep a resource tagged through its entire lifecycle.

Updating tags with the Lambda tag APIs

You can add and remove tags for supported Lambda resources through the [TagResource](#) and [UntagResource](#) API operations.

You can call these operations using the AWS CLI. To add tags to an existing resource, use the `tag-resource` command. This example adds two tags, one with the key *Department* and one with the key *CostCenter*.

```
aws lambda tag-resource \
  --resource arn:aws:lambda:us-east-2:123456789012:resource-type:my-resource \
  --tags Department=Marketing,CostCenter=1234ABCD
```

To remove tags, use the `untag-resource` command. This example removes the tag with the key *Department*.

```
aws lambda untag-resource --resource arn:aws:lambda:us-east-1:123456789012:resource-
type:resource-identifier \
  --tag-keys Department
```

Adding tags when creating a function

To create a new Lambda function with tags, use the [CreateFunction](#) API operation. Specify the `Tags` parameter. You can call this operation with the `create-function` CLI command and the `--tags` option. Before using the `tags` parameter with `CreateFunction`, ensure that your role has permission to tag resources alongside the usual permissions needed for this operation. For more information about permissions for tagging, see [the section called "Permissions required for working with tags"](#). This example adds two tags, one with the key *Department* and one with the key *CostCenter*.

```
aws lambda create-function --function-name my-function
  --handler index.js --runtime nodejs24.x \
  --role arn:aws:iam::123456789012:role/lambda-role \
```

```
--tags Department=Marketing, CostCenter=1234ABCD
```

Viewing tags on a function

To view the tags that are applied to a specific Lambda resource, use the `ListTags` API operation. For more information, see [ListTags](#).

You can call this operation with the `list-tags` AWS CLI command by providing an ARN (Amazon Resource Name).

```
aws lambda list-tags --resource arn:aws:lambda:us-east-1:123456789012:resource-type:resource-identifier
```

You can view the tags that are applied to a specific resource with the [GetFunction](#) API operation. Comparable functionality is not available for other resource types.

You can call this operation with the `get-function` CLI command:

```
aws lambda get-function --function-name my-function
```

Filtering resources by tag

You can use the AWS Resource Groups Tagging API [GetResources](#) API operation to filter your resources by tags. The `GetResources` operation receives up to 10 filters, with each filter containing a tag key and up to 10 tag values. You provide `GetResources` with a `ResourceType` to filter by specific resource types.

You can call this operation using the `get-resources` AWS CLI command. For examples of using `get-resources`, see [get-resources](#) in the *AWS CLI Command Reference*.

Response streaming for Lambda functions

Lambda functions can natively stream response payloads back to clients through [Lambda function URLs](#) or by using the [InvokeWithResponseStream](#) API (via the AWS SDK or direct API calls). Your Lambda function can also stream response payloads through the [Amazon API Gateway proxy integration](#), which uses the [InvokeWithResponseStream](#) API to invoke your function. Response streaming can benefit latency sensitive applications by improving time to first byte (TTFB) performance. This is because you can send partial responses back to the client as they become available. Additionally, response streaming functions can return payloads up to 200 MB, compared to the 6 MB maximum for buffered responses. Streaming a response also means that your function doesn't need to fit the entire response in memory. For very large responses, this can reduce the amount of memory you need to configure for your function.

Note

Lambda response streaming is not yet available in all AWS Regions. Please refer to Builder Center's [AWS Capabilities by Region](#) for feature availability by Region.

The speed at which Lambda streams your responses depends on the response size. The streaming rate for the first 6 MB of your function's response is uncapped. For responses larger than 6 MB, the remainder of the response is subject to a bandwidth cap. For more information on streaming bandwidth, see [Bandwidth limits for response streaming](#).

Streaming responses incur cost and streamed responses are not interrupted or stopped when the invoking client connection is broken. Customers will be billed for the full function duration, so customers should exercise caution when configuring long function timeouts.

Lambda supports response streaming on Node.js managed runtimes. For other languages, including Python, you can [use a custom runtime with a custom Runtime API integration](#) to stream responses or use the [Lambda Web Adapter](#).

Note

When testing your function through the Lambda console, you'll always see responses as buffered.

Topics

- [Bandwidth limits for response streaming](#)
- [VPC compatibility with response streaming](#)
- [Writing response streaming-enabled Lambda functions](#)
- [Invoking a response streaming enabled function using Lambda function URLs](#)
- [Tutorial: Creating a response streaming Lambda function with a function URL](#)

Bandwidth limits for response streaming

The first 6 MB of your function's response payload has uncapped bandwidth. After this initial burst, Lambda streams your response at a maximum rate of 2 MBps. If your function responses never exceed 6 MB, then this bandwidth limit never applies.

Note

Bandwidth limits only apply to your function's response payload, and not to network access by your function.

The rate of uncapped bandwidth varies depending on a number of factors, including your function's processing speed. You can normally expect a rate higher than 2 MBps for the first 6 MB of your function's response. If your function is streaming a response to a destination outside of AWS, the streaming rate also depends on the speed of the external internet connection.

VPC compatibility with response streaming

When using Lambda functions in a VPC environment, there are important considerations for response streaming:

- Lambda function URLs do not support response streaming within a VPC environment.
- You can use response streaming within a VPC by invoking your Lambda function through the AWS SDK using the `InvokeWithResponseStream` API. This requires setting up the appropriate VPC endpoints for Lambda.
- For VPC environments, you'll need to create an interface VPC endpoint for Lambda to enable communication between your resources in the VPC and the Lambda service.

A typical architecture for response streaming in a VPC might include:

Client in VPC -> Interface VPC endpoint for Lambda -> Lambda function -> Response streaming back through the same path

Writing response streaming-enabled Lambda functions

Writing the handler for response streaming functions is different than typical handler patterns. When writing streaming functions, be sure to do the following:

- Wrap your function with the `awsLambda.streamifyResponse()` decorator. The `awsLambda` global object is provided by Lambda's Node.js runtime environment.
- End the stream gracefully to ensure that all data processing is complete.

Configuring a handler function to stream responses

To indicate to the runtime that Lambda should stream your function's responses, you must wrap your function with the `streamifyResponse()` decorator. This tells the runtime to use the proper logic path for streaming responses and enables the function to stream responses.

The `streamifyResponse()` decorator accepts a function that accepts the following parameters:

- `event` – Provides information about the function URL's invocation event, such as the HTTP method, query parameters, and the request body.
- `responseStream` – Provides a writable stream.
- `context` – Provides methods and properties with information about the invocation, function, and execution environment.

The `responseStream` object is a [Node.js writableStream](#). As with any such stream, you should use the `pipeline()` method.

Note

The `awsLambda` global object is automatically provided by Lambda's Node.js runtime and no import is required.

Example response streaming-enabled handler

```
import { pipeline } from 'node:stream/promises';
import { Readable } from 'node:stream';

export const echo = awslambda.streamifyResponse(async (event, responseStream, _context)
=> {
  // As an example, convert event to a readable stream.
  const requestStream = Readable.from(Buffer.from(JSON.stringify(event)));

  await pipeline(requestStream, responseStream);
});
```

While `responseStream` offers the `write()` method to write to the stream, we recommend that you use [`pipeline\(\)`](#) wherever possible. Using `pipeline()` ensures that the writable stream is not overwhelmed by a faster readable stream.

Ending the stream

Make sure that you properly end the stream before the handler returns. The `pipeline()` method handles this automatically.

For other use cases, call the `responseStream.end()` method to properly end a stream. This method signals that no more data should be written to the stream. This method isn't required if you write to the stream with `pipeline()` or `pipe()`.

Starting with Node.js 24, Lambda no longer waits for unresolved promises to complete after your handler returns or the response stream ends. If your function depends on additional asynchronous operations, such as timers or fetches, you should `await` them in your handler.

Example ending a stream with `pipeline()`

```
import { pipeline } from 'node:stream/promises';

export const handler = awslambda.streamifyResponse(async (event, responseStream,
_context) => {
  await pipeline(requestStream, responseStream);
});
```

Example ending a stream without pipeline()

```
export const handler = awslambda.streamifyResponse(async (event, responseStream,
_context) => {
  responseStream.write("Hello ");
  responseStream.write("world ");
  responseStream.write("from ");
  responseStream.write("Lambda!");
  responseStream.end();
});
```

Invoking a response streaming enabled function using Lambda function URLs

Note

Your Lambda function can now stream response payloads through the [Amazon API Gateway proxy integration](#).

You can invoke response streaming enabled functions by changing the invoke mode of your function's URL. The invoke mode determines which API operation Lambda uses to invoke your function. The available invoke modes are:

- **BUFFERED** – This is the default option. Lambda invokes your function using the Invoke API operation. Invocation results are available when the payload is complete. The maximum payload size is 6 MB.
- **RESPONSE_STREAM** – Enables your function to stream payload results as they become available. Lambda invokes your function using the InvokeWithResponseStream API operation. The maximum response payload size is 200 MB.

You can still invoke your function without response streaming by directly calling the Invoke API operation. However, Lambda streams all response payloads for invocations that come through the function's URL until you change the invoke mode to **BUFFERED**.

Console

To set the invoke mode of a function URL (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to set the invoke mode for.
3. Choose the **Configuration** tab, and then choose **Function URL**.
4. Choose **Edit**, then choose **Additional settings**.
5. Under **Invoke mode**, choose your desired invoke mode.
6. Choose **Save**.

AWS CLI

To set the invoke mode of a function's URL (AWS CLI)

```
aws lambda update-function-url-config \  
  --function-name my-function \  
  --invoke-mode RESPONSE_STREAM
```

CloudFormation

To set the invoke mode of a function's URL (CloudFormation)

```
MyFunctionUrl:  
  Type: AWS::Lambda::Url  
  Properties:  
    AuthType: AWS_IAM  
    InvokeMode: RESPONSE_STREAM
```

For more information about configuring function URLs, see [Lambda function URLs](#).

Tutorial: Creating a response streaming Lambda function with a function URL

In this tutorial, you create a Lambda function defined as a .zip file archive with a function URL endpoint that returns a response stream. For more information about configuring function URLs, see [Function URLs](#).

Prerequisites

This tutorial assumes that you have some knowledge of basic Lambda operations and the Lambda console. If you haven't already, follow the instructions in [Create a Lambda function with the console](#) to create your first Lambda function.

To complete the following steps, you need the [AWS CLI version 2](#). Commands and the expected output are listed in separate blocks:

```
aws --version
```

You should see the following output:

```
aws-cli/2.13.27 Python/3.11.6 Linux/4.14.328-248.540.amzn2.x86_64 exe/x86_64.amzn.2
```

For long commands, an escape character (\) is used to split a command over multiple lines.

On Linux and macOS, use your preferred shell and package manager.

Note

In Windows, some Bash CLI commands that you commonly use with Lambda (such as `zip`) are not supported by the operating system's built-in terminals. To get a Windows-integrated version of Ubuntu and Bash, [install the Windows Subsystem for Linux](#). Example CLI commands in this guide use Linux formatting. Commands which include inline JSON documents must be reformatted if you are using the Windows CLI.

Create an execution role

Create the [execution role](#) that gives your Lambda function permission to access AWS resources.

To create an execution role

1. Open the [Roles page](#) of the AWS Identity and Access Management (IAM) console.
2. Choose **Create role**.
3. Create a role with the following properties:
 - **Trusted entity type** – AWS service
 - **Use case** – Lambda

- **Permissions – `AWSLambdaBasicExecutionRole`**
- **Role name – `response-streaming-role`**

The **`AWSLambdaBasicExecutionRole`** policy has the permissions that the function needs to write logs to Amazon CloudWatch Logs. After you create the role, note down the its Amazon Resource Name (ARN). You'll need it in the next step.

Create a response streaming function (AWS CLI)

Create a response streaming Lambda function with a function URL endpoint using the AWS Command Line Interface (AWS CLI).

To create a function that can stream responses

1. Copy the following code example into a file named `index.js`. This function streams three responses, separated by 1 second.

```
exports.handler = awslambda.streamifyResponse(
  async (event, responseStream, _context) => {
    // Metadata is a JSON serializable JS object. Its shape is not defined here.
    const metadata = {
      statusCode: 200,
      headers: {
        "Content-Type": "application/json",
        "CustomHeader": "outerspace"
      }
    };

    // Assign to the responseStream parameter to prevent accidental reuse of the non-
    wrapped stream.
    responseStream = awslambda.HttpResponseStream.from(responseStream, metadata);

    responseStream.write("Streaming with Helper \n");
    await new Promise(r => setTimeout(r, 1000));
    responseStream.write("Hello 0 \n");
    await new Promise(r => setTimeout(r, 1000));
    responseStream.write("Hello 1 \n");
    await new Promise(r => setTimeout(r, 1000));
    responseStream.write("Hello 2 \n");
    await new Promise(r => setTimeout(r, 1000));
    responseStream.end();
  }
);
```

```
    await responseStream.finished();
  }
};
```

2. Create a deployment package.

```
zip function.zip index.js
```

3. Create a Lambda function with the `create-function` command. Replace the value of `--role` with the role ARN from the previous step. This command sets the function timeout to 10 seconds, which allows the function to stream three responses.

```
aws lambda create-function \
  --function-name my-streaming-function \
  --runtime nodejs24.x \
  --zip-file fileb://function.zip \
  --handler index.handler \
  --timeout 10 \
  --role arn:aws:iam::123456789012:role/response-streaming-role
```

To create a function URL

1. Add a resource-based policy to your function that grants `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions. Each statement must be added in a separate command. Replace the value of `--principal` with your AWS account ID.

```
aws lambda add-permission \
  --function-name my-streaming-function \
  --action lambda:InvokeFunctionUrl \
  --statement-id UrlPolicyInvokeURL \
  --principal 123456789012 \
  --function-url-auth-type AWS_IAM
```

```
aws lambda add-permission \
  --function-name my-streaming-function \
  --action lambda:InvokeFunction \
  --statement-id UrlPolicyInvokeFunction \
  --principal 123456789012
```

2. Create a URL endpoint for the function with the `create-function-url-config` command.

```
aws lambda create-function-url-config \  
  --function-name my-streaming-function \  
  --auth-type AWS_IAM \  
  --invoke-mode RESPONSE_STREAM
```

Note

If you get an error about `--invoke-mode`, you might need to upgrade to a [newer version of the AWS CLI](#).

Test the function URL endpoint

Test your integration by invoking your function. You can open your function's URL in a browser, or you can use curl.

```
curl --request GET "https://abcdefghijklm7nop7qrs740abcd.lambda-url.us-east-1.on.aws/"  
  --user "AKIAIOSFODNN7EXAMPLE" --aws-sigv4 "aws:amz:us-east-1:lambda" --no-buffer
```

Our function URL uses the `IAM_AUTH` authentication type. This means that you need to sign requests with both your [AWS access key and secret key](#). In the previous command, replace `AKIAIOSFODNN7EXAMPLE` with the AWS access key ID. Enter your AWS secret key when prompted. If you don't have your AWS secret key, you can [use temporary AWS credentials](#) instead.

You should see a response like this:

```
Streaming with Helper  
Hello 0  
Hello 1  
Hello 2
```

Clean up your resources

You can now delete the resources that you created for this tutorial, unless you want to retain them. By deleting AWS resources that you're no longer using, you prevent unnecessary charges to your AWS account.

To delete the execution role

1. Open the [Roles page](#) of the IAM console.
2. Select the execution role that you created.
3. Choose **Delete**.
4. Enter the name of the role in the text input field and choose **Delete**.

To delete the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Select the function that you created.
3. Choose **Actions, Delete**.
4. Type **confirm** in the text input field and choose **Delete**.

Understanding Lambda function invocation methods

After you deploy your Lambda function, you can invoke it in several ways:

- The [Lambda console](#) – Use the Lambda console to quickly create a test event to invoke your function.
- The [AWS SDK](#) – Use the AWS SDK to programmatically invoke your function.
- The [Invoke](#) API – Use the Lambda Invoke API to directly invoke your function.
- The [AWS Command Line Interface \(AWS CLI\)](#) – Use the `aws lambda invoke` AWS CLI command to directly invoke your function from the command line.
- A [function URL HTTP\(S\) endpoint](#) – Use function URLs to create a dedicated HTTP(S) endpoint that you can use to invoke your function.

All of these methods are *direct* ways to invoke your function. In Lambda, a common use case is to invoke your function based on an event that occurs elsewhere in your application. Some services can invoke a Lambda function with each new event. This is called a [trigger](#). For stream and queue-based services, Lambda invokes the function with batches of records. This is called an [event source mapping](#).

When you invoke a function, you can choose to invoke it synchronously or asynchronously. With [synchronous invocation](#), you wait for the function to process the event and return a response. With [asynchronous invocation](#), Lambda queues the event for processing and returns a response immediately. The [InvocationType request parameter in the Invoke API](#) determines how Lambda invokes your function. A value of `RequestResponse` indicates synchronous invocation, and a value of `Event` indicates asynchronous invocation.

To invoke your function over IPv6, use Lambda's public [dual-stack endpoints](#). Dual-stack endpoints support both IPv4 and IPv6. Lambda dual-stack endpoints use the following syntax:

```
protocol://lambda.us-east-1.api.aws
```

You can also use [Lambda function URLs](#) to invoke functions over IPv6. Function URL endpoints have the following format:

```
https://url-id.lambda-url.us-east-1.on.aws
```

If the function invocation results in an error, for synchronous invocations, view the error message in the response and retry the invocation manually. For asynchronous invocations, Lambda handles retries automatically and can send invocation records to a [destination](#).

Invoke a Lambda function synchronously

When you invoke a function synchronously, Lambda runs the function and waits for a response. When the function completes, Lambda returns the response from the function's code with additional data, such as the version of the function that was invoked. To invoke a function synchronously with the AWS CLI, use the `invoke` command.

```
aws lambda invoke --function-name my-function \  
  --cli-binary-format raw-in-base64-out \  
  --payload '{ "key": "value" }' response.json
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
{  
  "ExecutedVersion": "$LATEST",  
  "StatusCode": 200  
}
```

The following diagram shows clients invoking a Lambda function synchronously. Lambda sends the events directly to the function and sends the function's response back to the invoker.

Synchronous Invocation

The `payload` is a string that contains an event in JSON format. The name of the file where the AWS CLI writes the response from the function is `response.json`. If the function returns an

object or error, the response body is the object or error in JSON format. If the function exits without error, the response body is `null`.

Note

Lambda does not wait for external extensions to complete before sending the response. External extensions run as independent processes in the execution environment and continue to run after the function invocation is complete. For more information, see [Augment Lambda functions using Lambda extensions](#).

The output from the command, which is displayed in the terminal, includes information from headers in the response from Lambda. This includes the version that processed the event (useful when you use [aliases](#)), and the status code returned by Lambda. If Lambda was able to run the function, the status code is 200, even if the function returned an error.

Note

For functions with a long timeout, your client might be disconnected during synchronous invocation while it waits for a response. Configure your HTTP client, SDK, firewall, proxy, or operating system to allow for long connections with timeout or keep-alive settings.

If Lambda isn't able to run the function, the error is displayed in the output.

```
aws lambda invoke --function-name my-function \  
  --cli-binary-format raw-in-base64-out \  
  --payload value response.json
```

You should see the following output:

```
An error occurred (InvalidRequestContentException) when calling the Invoke operation:  
Could not parse request body into json: Unrecognized token 'value': was expecting  
( 'true', 'false' or 'null' )  
at [Source: (byte[])"value"; line: 1, column: 11]
```

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElkOiA4N2QwNDRIOC1mMTU0LTExZTgtOGNkYS0yOTc0YzVlNGZiMjEgVmVyc2l1vb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **`cli-binary-format`** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
```

```
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8  Duration: 79.67 ms    Billed
Duration: 80 ms      Memory Size: 128 MB      Max Memory Used: 73 MB
```

The base64 utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

For more information about the Invoke API, including a full list of parameters, headers, and errors, see [Invoke](#).

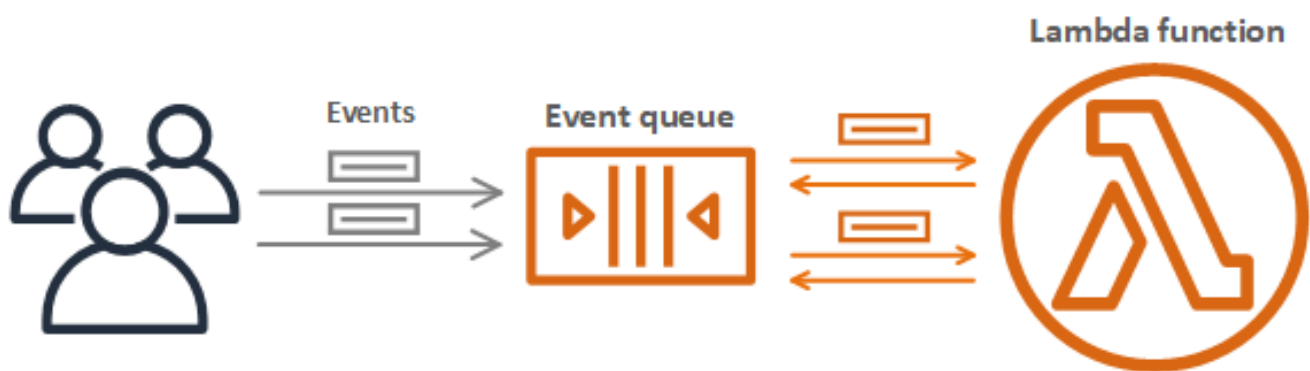

When you invoke a function directly, you can check the response for errors and retry. The AWS CLI and AWS SDK also automatically retry on client timeouts, throttling, and service errors. For more information, see [Understanding retry behavior in Lambda](#).

Invoking a Lambda function asynchronously

Several AWS services, such as Amazon Simple Storage Service (Amazon S3) and Amazon Simple Notification Service (Amazon SNS), invoke functions asynchronously to process events. You can also invoke a Lambda function asynchronously using the AWS Command Line Interface (AWS CLI) or one of the AWS SDKs. When you invoke a function asynchronously, you don't wait for a response from the function code. You hand off the event to Lambda and Lambda handles the rest. You can configure how Lambda handles errors, and can send invocation records to a downstream resource such as Amazon Simple Queue Service (Amazon SQS) or Amazon EventBridge (EventBridge) to chain together components of your application.

The following diagram shows clients invoking a Lambda function asynchronously. Lambda queues the events before sending them to the function.

Asynchronous Invocation

For asynchronous invocation, Lambda places the event in a queue and returns a success response without additional information. A separate process reads events from the queue and sends them to your function.

To invoke a Lambda function asynchronously using the AWS Command Line Interface (AWS CLI) or one of the AWS SDKs, set the [InvocationType](#) parameter to Event. The following example shows an AWS CLI command to invoke a function.

```
aws lambda invoke \  
  --function-name my-function \  
  --invocation-type Event \  
  --cli-binary-format raw-in-base64-out \
```

```
--payload '{ "key": "value" }' response.json
```

You should see the following output:

```
{  
  "StatusCode": 202  
}
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

The output file (`response.json`) doesn't contain any information, but is still created when you run this command. If Lambda isn't able to add the event to the queue, the error message appears in the command output.

How Lambda handles errors and retries with asynchronous invocation

Lambda manages your function's asynchronous event queue and attempts to retry on errors. If the function returns an error, by default Lambda attempts to run it two more times, with a one-minute wait between the first two attempts, and two minutes between the second and third attempts. Function errors include errors returned by the function's code and errors returned by the function's runtime, such as timeouts.

If the function doesn't have enough concurrency available to process all events, additional requests are throttled. For throttling errors (429) and system errors (500-series), Lambda returns the event to the queue and attempts to run the function again for up to 6 hours by default. The retry interval increases exponentially from 1 second after the first attempt to a maximum of 5 minutes. If the queue contains many entries, Lambda increases the retry interval and reduces the rate at which it reads events from the queue.

Even if your function doesn't return an error, it's possible for it to receive the same event from Lambda multiple times because the queue itself is eventually consistent. If the function can't keep up with incoming events, events might also be deleted from the queue without being sent to the function. Ensure that your function code gracefully handles duplicate events, and that you have enough concurrency available to handle all invocations.

When the queue is very long, new events might age out before Lambda has a chance to send them to your function. When an event expires or fails all processing attempts, Lambda discards it. You can [configure error handling](#) for a function to reduce the number of retries that Lambda performs, or to discard unprocessed events more quickly. To capture discarded events, [configure a dead-letter queue](#) for the function. To capture records of failed invocations (such as timeouts or runtime errors), [create an on-failure destination](#).

Configuring error handling settings for Lambda asynchronous invocations

Use the following settings to configure how Lambda handles errors and retries for asynchronous function invocations:

- [MaximumEventAgeInSeconds](#): The maximum amount of time, in seconds, that Lambda keeps an event in the asynchronous event queue before discarding it.
- [MaximumRetryAttempts](#): The maximum number of times that Lambda retries events when the function returns an error.

Use the Lambda console or AWS CLI to configure error handling settings on a function, a version, or an alias.

Console

To configure error handling

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Asynchronous invocation**.
4. Under **Asynchronous invocation**, choose **Edit**.
5. Configure the following settings.
 - **Maximum age of event** – The maximum amount of time Lambda retains an event in the asynchronous event queue, up to 6 hours.
 - **Retry attempts** – The number of times Lambda retries when the function returns an error, between 0 and 2.
6. Choose **Save**.

AWS CLI

To configure asynchronous invocation with the AWS CLI, use the [put-function-event-invoke-config](#) command. The following example configures a function with a maximum event age of 1 hour and no retries.

```
aws lambda put-function-event-invoke-config \  
  --function-name error \  
  --maximum-event-age-in-seconds 3600 \  
  --maximum-retry-attempts 0
```

The `put-function-event-invoke-config` command overwrites any existing configuration on the function, version, or alias. To configure an option without resetting others, use [update-function-event-invoke-config](#). The following example configures Lambda to send a record to a standard SQS queue named `destination` when an event can't be processed.

```
aws lambda update-function-event-invoke-config \  
  --function-name my-function \  
  --destination-config '{"OnFailure":{"Destination": "arn:aws:sqs:us-east-1:123456789012:destination"}}'
```

You should see the following output:

```
{  
  "LastModified": 1573686021.479,  
  "FunctionArn": "arn:aws:lambda:us-east-1:123456789012:function:my-function:  
$LATEST",  
  "MaximumRetryAttempts": 0,  
  "MaximumEventAgeInSeconds": 3600,  
  "DestinationConfig": {  
    "OnSuccess": {},  
    "OnFailure": {}  
  }  
}
```

When an invocation event exceeds the maximum age or fails all retry attempts, Lambda discards it. To retain a copy of discarded events, configure a failed-event [destination](#).

Capturing records of Lambda asynchronous invocations

Lambda can send records of asynchronous invocations to one of the following AWS services.

- **Amazon SQS** – A standard SQS queue
- **Amazon SNS** – A standard SNS topic
- **Amazon S3** – An Amazon S3 bucket (on failure only)
- **AWS Lambda** – A Lambda function
- **Amazon EventBridge** – An EventBridge event bus

The invocation record contains details about the request and response in JSON format. You can configure separate destinations for events that are processed successfully, and events that fail all processing attempts. Alternatively, you can configure a standard Amazon SQS queue or standard Amazon SNS topic as a dead-letter queue for discarded events. For dead-letter queues, Lambda only sends the content of the event, without details about the response.

If Lambda can't send a record to a destination you have configured, it sends a `DestinationDeliveryFailures` metric to Amazon CloudWatch. This can happen if your configuration includes an unsupported destination type, such as an Amazon SQS FIFO queue or an Amazon SNS FIFO topic. Delivery errors can also occur due to permissions errors and size limits. For more information on Lambda invocation metrics, see [the section called "Invocation metrics"](#).

Note

To prevent a function from triggering, you can set the function's reserved concurrency to zero. When you set reserved concurrency to zero for an asynchronously invoked function, Lambda begins sending new events to the configured [dead-letter queue](#) or the on-failure [event destination](#), without any retries. To process events that were sent while reserved concurrency was set to zero, you must consume the events from the dead-letter queue or the on-failure event destination.

Adding a destination

To retain records of asynchronous invocations, add a destination to your function. You can choose to send either successful or failed invocations to a destination. Each function can have multiple destinations, so you can configure separate destinations for successful and failed events. Each

record sent to the destination is a JSON document with details about the invocation. Like error handling settings, you can configure destinations on a function, function version, or alias.

Tip

You can also retain records of failed invocations for the following event source mapping types: [Amazon Kinesis](#), [Amazon DynamoDB](#), and [Apache Kafka \(Amazon MSK and self-managed Apache Kafka\)](#).

The following table lists supported destinations for asynchronous invocation records. For Lambda to successfully send records to your chosen destination, ensure that your function's [execution role](#) also contains the relevant permissions. The table also describes how each destination type receives the JSON invocation record.

Destination type	Required permission	Destination-specific JSON format
Amazon SQS queue	sqs:SendMessage	Lambda passes the invocation record as the Message to the destination.
Amazon SNS topic	sns:Publish	Lambda passes the invocation record as the Message to the destination.
Amazon S3 bucket (on failure only)	s3:PutObject s3:ListBucket	<ul style="list-style-type: none"> Lambda stores the invocation record as a JSON object in the destination bucket. The S3 object name uses the following naming convention: <pre>aws/lambda/async/< function-name>/YYY Y/MM/DD/YYYY-MM-DD</pre>

Destination type	Required permission	Destination-specific JSON format
		THH.MM.SS-<Random UUID>
Lambda function	lambda:InvokeFunction	Lambda passes the invocation record as the payload to the function.
EventBridge	events:PutEvents	<ul style="list-style-type: none"> • Lambda passes the invocation record as the detail in the PutEvents call. • The value for the source event field is <code>lambda</code>. • The value for the detail-type event field is either "Lambda Function Invocation Result - Success" or "Lambda Function Invocation Result - Failure". • The resource event field contains the function and destination Amazon Resource Names (ARNs). • For other event fields, see Amazon EventBridge events.

Note

For Amazon S3 destinations, if you have enabled encryption on the bucket using a KMS key, your function also needs the [kms:GenerateDataKey](#) permission.

Important

When using Amazon SNS as a destination, be aware that Amazon SNS has a maximum message size limit of 256 KB. If your async invocation payload approaches 1 MB, the invocation record (which includes the original payload plus additional metadata) may exceed the Amazon SNS limit and cause delivery failures. Consider using Amazon SQS or Amazon S3 destinations for larger payloads.

The following steps describe how to configure a destination for a function using the Lambda console and the AWS CLI.

Console

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Under **Function overview**, choose **Add destination**.
4. For **Source**, choose **Asynchronous invocation**.
5. For **Condition**, choose from the following options:
 - **On failure** – Send a record when the event fails all processing attempts or exceeds the maximum age.
 - **On success** – Send a record when the function successfully processes an asynchronous invocation.
6. For **Destination type**, choose the type of resource that receives the invocation record.
7. For **Destination**, choose a resource.
8. Choose **Save**.

AWS CLI

To configure a destination using the AWS CLI, run the [update-function-event-invoke-config](#) command. The following example configures Lambda to send a record to a standard SQS queue named destination when an event can't be processed.

```
aws lambda update-function-event-invoke-config \  
  --function-name my-function \  
  --event-invoke-config '{"Destination": "destination", "Condition": "On failure"}'
```

```
--destination-config '{"OnFailure":{"Destination": "arn:aws:sqs:us-east-1:123456789012:destination"}}'
```

Security best practices for Amazon S3 destinations

Deleting an S3 bucket that's configured as a destination without removing the destination from your function's configuration can create a security risk. If another user knows your destination bucket's name, they can recreate the bucket in their AWS account. Records of failed invocations will be sent to their bucket, potentially exposing data from your function.

Warning

To ensure that invocation records from your function can't be sent to an S3 bucket in another AWS account, add a condition to your function's execution role that limits `s3:PutObject` permissions to buckets in your account.

The following example shows an IAM policy that limits your function's `s3:PutObject` permissions to buckets in your account. This policy also gives Lambda the `s3:ListBucket` permission it needs to use an S3 bucket as a destination.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "S3BucketResourceAccountWrite",
      "Effect": "Allow",
      "Action": [
        "s3:PutObject",
        "s3:ListBucket"
      ],
      "Resource": [
        "arn:aws:s3:::*/*",
        "arn:aws:s3:::*"
      ],
      "Condition": {
        "StringEquals": {
          "s3:ResourceAccount": "111122223333"
        }
      }
    }
  ]
}
```

```
    }  
  ]  
}
```

To add a permissions policy to your function's execution role using the AWS Management Console or AWS CLI, refer to the instructions in the following procedures:

Console

To add a permissions policy to a function's execution role (console)

1. Open the [Functions page](#) of the Lambda console.
2. Select the Lambda function whose execution role you want to modify.
3. In the **Configuration** tab, select **Permissions**.
4. In the **Execution role** tab, select your function's **Role name** to open the role's IAM console page.
5. Add a permissions policy to the role by doing the following:
 - a. In the **Permissions policies** pane, choose **Add permissions** and select **Create inline policy**.
 - b. In **Policy editor**, select **JSON**.
 - c. Paste the policy you want to add into the editor (replacing the existing JSON), and then choose **Next**.
 - d. Under **Policy details**, enter a **Policy name**.
 - e. Choose **Create policy**.

AWS CLI

To add a permissions policy to a function's execution role (CLI)

1. Create a JSON policy document with the required permissions and save it in a local directory.
2. Use the IAM `put-role-policy` CLI command to add the permissions to your function's execution role. Run the following command from the directory you saved your JSON policy document in and replace the role name, policy name, and policy document with your own values.

```
aws iam put-role-policy \  
--role-name my_lambda_role \  
--policy-name LambdaS3DestinationPolicy \  
--policy-document file://my_policy.json
```

Example invocation record

When an invocation matches the condition, Lambda sends [a JSON document](#) with details about the invocation to the destination. The following example shows an invocation record for an event that failed three processing attempts due to a function error.

Example

```
{  
  "version": "1.0",  
  "timestamp": "2019-11-14T18:16:05.568Z",  
  "requestContext": {  
    "requestId": "e4b46cbf-b738-xmpl-8880-a18cdf61200e",  
    "functionArn": "arn:aws:lambda:us-east-1:123456789012:function:my-function:  
$LATEST",  
    "condition": "RetriesExhausted",  
    "approximateInvokeCount": 3  
  },  
  "requestPayload": {  
    "ORDER_IDS": [  
      "9e07af03-ce31-4ff3-xmpl-36dce652cb4f",  
      "637de236-e7b2-464e-xmpl-baf57f86bb53",  
      "a81ddca6-2c35-45c7-xmpl-c3a03a31ed15"  
    ]  
  },  
  "responseContext": {  
    "statusCode": 200,  
    "executedVersion": "$LATEST",  
    "functionError": "Unhandled"  
  },  
  "responsePayload": {  
    "errorMessage": "RequestId: e4b46cbf-b738-xmpl-8880-a18cdf61200e Process exited  
before completing request"  
  }  
}
```

The invocation record contains details about the event, the response, and the reason that the record was sent.

Tracing requests to destinations

You can use AWS X-Ray to see a connected view of each request as it's queued, processed by a Lambda function, and passed to the destination service. When you activate X-Ray tracing for a function or a service that invokes a function, Lambda adds an X-Ray header to the request and passes the header to the destination service. Traces from upstream services are automatically linked to traces from downstream Lambda functions and destination services, creating an end-to-end view of the entire application. For more information about tracing, see [Visualize Lambda function invocations using AWS X-Ray](#).

Adding a dead-letter queue

As an alternative to an [on-failure destination](#), you can configure your function with a dead-letter queue to save discarded events for further processing. A dead-letter queue acts the same as an on-failure destination in that it is used when an event fails all processing attempts or expires without being processed. However, you can only add or remove a dead-letter queue at the function level. Function versions use the same dead-letter queue settings as the unpublished version (\$LATEST). On-failure destinations also support additional targets and include details about the function's response in the invocation record.

To reprocess events in a dead-letter queue, you can set it as an [event source](#) for your Lambda function. Alternatively, you can manually retrieve the events.

You can choose an Amazon SQS standard queue or Amazon SNS standard topic for your dead-letter queue. FIFO queues and Amazon SNS FIFO topics are not supported.

- [Amazon SQS queue](#) – A queue holds failed events until they're retrieved. Choose an Amazon SQS standard queue if you expect a single entity, such as a Lambda function or CloudWatch alarm, to process the failed event. For more information, see [Using Lambda with Amazon SQS](#).
- [Amazon SNS topic](#) – A topic relays failed events to one or more destinations. Choose an Amazon SNS standard topic if you expect multiple entities to act on a failed event. For example, you can configure a topic to send events to an email address, a Lambda function, and/or an HTTP endpoint. For more information, see [Invoking Lambda functions with Amazon SNS notifications](#).

To send events to a queue or topic, your function needs additional permissions. Add a policy with the [required permissions](#) to your function's [execution role](#). If the target queue or topic is encrypted

with a customer managed AWS KMS key, ensure that both your function's execution role and the key's [resource-based policy](#) contains the relevant permissions.

After creating the target and updating your function's execution role, add the dead-letter queue to your function. You can configure multiple functions to send events to the same target.

Console

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Asynchronous invocation**.
4. Under **Asynchronous invocation**, choose **Edit**.
5. Set **Dead-letter queue service** to **Amazon SQS** or **Amazon SNS**.
6. Choose the target queue or topic.
7. Choose **Save**.

AWS CLI

To configure a dead-letter queue with the AWS CLI, use the [update-function-configuration](#) command.

```
aws lambda update-function-configuration \  
  --function-name my-function \  
  --dead-letter-config TargetArn=arn:aws:sns:us-east-1:123456789012:my-topic
```

Lambda sends the event to the dead-letter queue as-is, with additional information in attributes. You can use this information to identify the error that the function returned, or to correlate the event with logs or an AWS X-Ray trace.

Dead-letter queue message attributes

- **RequestID** (String) – The ID of the invocation request. Request IDs appear in function logs. You can also use the X-Ray SDK to record the request ID on an attribute in the trace. You can then search for traces by request ID in the X-Ray console.
- **ErrorCode** (Number) – The HTTP status code.
- **ErrorMessage** (String) – The first 1 KB of the error message.

If Lambda can't send a message to the dead-letter queue, it deletes the event and emits the [DeadLetterErrors](#) metric. This can happen because of lack of permissions, or if the total size of the message exceeds the limit for the target queue or topic. For example, say that an Amazon SNS notification with a body close to 1 MB in size triggers a function that results in an error. In that case, the event data that Amazon SNS adds, combined with the attributes that Lambda adds, can cause the message to exceed the maximum size allowed in the dead-letter queue.

If you're using Amazon SQS as an event source, configure a dead-letter queue on the Amazon SQS queue itself and not on the Lambda function. For more information, see [Using Lambda with Amazon SQS](#).

Invoking durable Lambda functions

Durable Lambda functions can be invoked using the same methods as default Lambda functions, but with important considerations for long-running executions. This section covers invocation patterns, execution management, and best practices for durable functions.

Synchronous invocation limits

Synchronous invocations of durable Lambda functions are limited to 15 minutes, the same as default Lambda functions. If your durable function needs to run longer than 15 minutes, it must be invoked asynchronously.

When to use synchronous invocation: Use for durable functions that complete within 15 minutes and when you need immediate results, such as quick approval workflows or short data processing tasks.

Asynchronous invocation for long-running workflows

For durable functions that may run longer than 15 minutes, use asynchronous invocation. This allows the function to continue running while your client receives an immediate acknowledgment.

TypeScript

```
import { LambdaClient, InvokeCommand } from "@aws-sdk/client-lambda";

const client = new LambdaClient({});

// Asynchronous invocation
const command = new InvokeCommand({
  FunctionName: "my-durable-function",
  InvocationType: "Event", // Asynchronous
  Payload: JSON.stringify({ orderId: "12345" })
});

await client.send(command);
```

Python

```
import boto3
import json

client = boto3.client('lambda')

# Asynchronous invocation
response = client.invoke(
    FunctionName='my-durable-function',
    InvocationType='Event', # Asynchronous
    Payload=json.dumps({'order_id': '12345'})
)
```

Execution management APIs

Lambda provides APIs to manage and monitor durable function executions, including listing executions, getting execution status, and stopping running executions.

TypeScript

```
// Get execution status
const statusCommand = new InvokeCommand({
  FunctionName: "my-durable-function",
  InvocationType: "RequestResponse",
  Payload: JSON.stringify({
    action: "getStatus",
    executionId: "exec-123"
  })
});

const result = await client.send(statusCommand);
```

Python

```
# Get execution status
response = client.invoke(
    FunctionName='my-durable-function',
    InvocationType='RequestResponse',
    Payload=json.dumps({
```

```
        'action': 'get_status',  
        'execution_id': 'exec-123'  
    })  
)
```

How Lambda processes records from stream and queue-based event sources

An *event source mapping* is a Lambda resource that reads items from stream and queue-based services and invokes a function with batches of records. Within an event source mapping, resources called *event pollers* actively poll for new messages and invoke functions. By default, Lambda automatically scales event pollers, but for certain event source types, you can use [provisioned mode](#) to control the minimum and maximum number of event pollers dedicated to your event source mapping.

The following services use event source mappings to invoke Lambda functions:

- [Amazon DocumentDB \(with MongoDB compatibility\) \(Amazon DocumentDB\)](#)
- [Amazon DynamoDB](#)
- [Amazon Kinesis](#)
- [Amazon MQ](#)
- [Amazon Managed Streaming for Apache Kafka \(Amazon MSK\)](#)
- [Self-managed Apache Kafka](#)
- [Amazon Simple Queue Service \(Amazon SQS\)](#)

Warning

Lambda event source mappings process each event at least once, and duplicate processing of records can occur. To avoid potential issues related to duplicate events, we strongly recommend that you make your function code idempotent. To learn more, see [How do I make my Lambda function idempotent](#) in the AWS Knowledge Center.

How event source mappings differ from direct triggers

Some AWS services can directly invoke Lambda functions using *triggers*. These services push events to Lambda, and the function is invoked immediately when the specified event occurs. Triggers are suitable for discrete events and real-time processing. When you [create a trigger using the Lambda console](#), the console interacts with the corresponding AWS service to configure the event notification on that service. The trigger is actually stored and managed by the service that

generates the events, not by Lambda. Here are some examples of services that use triggers to invoke Lambda functions:

- **Amazon Simple Storage Service (Amazon S3):** Invokes a function when an object is created, deleted, or modified in a bucket. For more information, see [Tutorial: Using an Amazon S3 trigger to invoke a Lambda function](#).
- **Amazon Simple Notification Service (Amazon SNS):** Invokes a function when a message is published to an SNS topic. For more information, see [Tutorial: Using AWS Lambda with Amazon Simple Notification Service](#).
- **Amazon API Gateway:** Invokes a function when an API request is made to a specific endpoint. For more information, see [Invoking a Lambda function using an Amazon API Gateway endpoint](#).

Event source mappings are Lambda resources created and managed within the Lambda service. Event source mappings are designed for processing high-volume streaming data or messages from queues. Processing records from a stream or queue in batches is more efficient than processing records individually.

Batching behavior

By default, an event source mapping batches records together into a single payload that Lambda sends to your function. To fine-tune batching behavior, you can configure a batching window ([MaximumBatchingWindowInSeconds](#)) and a batch size ([BatchSize](#)). A batching window is the maximum amount of time to gather records into a single payload. A batch size is the maximum number of records in a single batch. Lambda invokes your function when one of the following three criteria is met:

- **The batching window reaches its maximum value.** Default batching window behavior varies depending on the specific event source.
 - **For Kinesis, DynamoDB, and Amazon SQS event sources:** The default batching window is 0 seconds. This means that Lambda invokes your function as soon as records are available. To set a batching window, configure `MaximumBatchingWindowInSeconds`. You can set this parameter to any value from 0 to 300 seconds in increments of 1 second. If you configure a batching window, the next window begins as soon as the previous function invocation completes.
 - **For Amazon MSK, self-managed Apache Kafka, Amazon MQ, and Amazon DocumentDB event sources:** The default batching window is 500 ms. You can configure `MaximumBatchingWindowInSeconds` to any value from 0 seconds to 300 seconds in

increments of seconds. In provisioned mode for Kafka event source mappings, when you configure a batching window, the next window begins as soon as the previous batch is completed. In non-provisioned Kafka event source mappings, when you configure a batching window, the next window begins as soon as the previous function invocation completes. To minimize latency when using Kafka event source mappings in provisioned mode, set `MaximumBatchingWindowInSeconds` to 0. This setting ensures that Lambda will start processing the next batch immediately after completing the current function invocation. For additional information on low latency processing, see [Low latency Apache Kafka](#).

- **For Amazon MQ and Amazon DocumentDB event sources:** The default batching window is 500 ms. You can configure `MaximumBatchingWindowInSeconds` to any value from 0 seconds to 300 seconds in increments of seconds. A batching window begins as soon as the first record arrives.

 **Note**

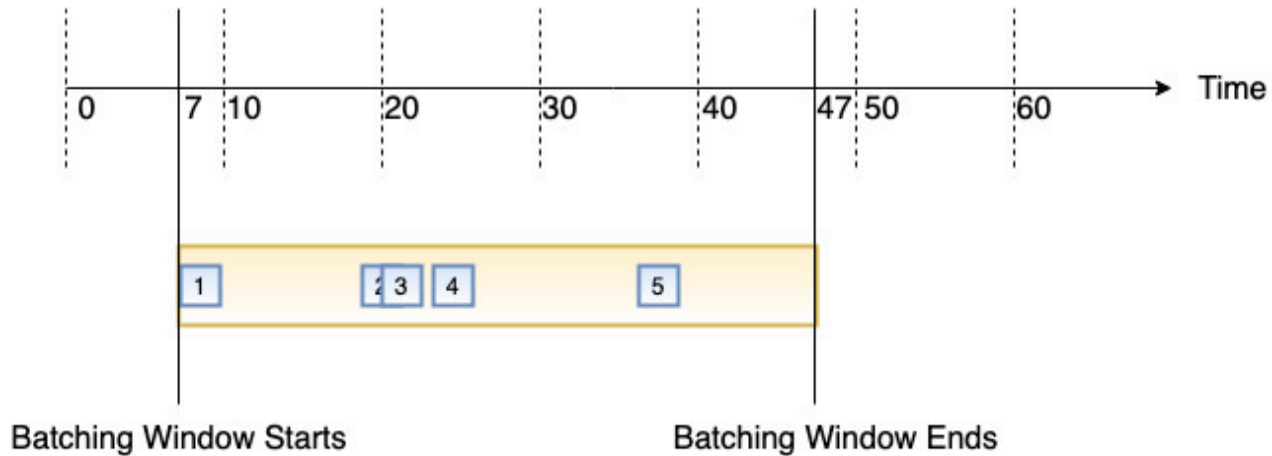

Because you can only change `MaximumBatchingWindowInSeconds` in increments of seconds, you cannot revert to the 500 ms default batching window after you have changed it. To restore the default batching window, you must create a new event source mapping.

- **The batch size is met.** The minimum batch size is 1. The default and maximum batch size depend on the event source. For details about these values, see the [BatchSize](#) specification for the `CreateEventSourceMapping` API operation.
- **The payload size reaches [6 MB](#).** You cannot modify this limit.

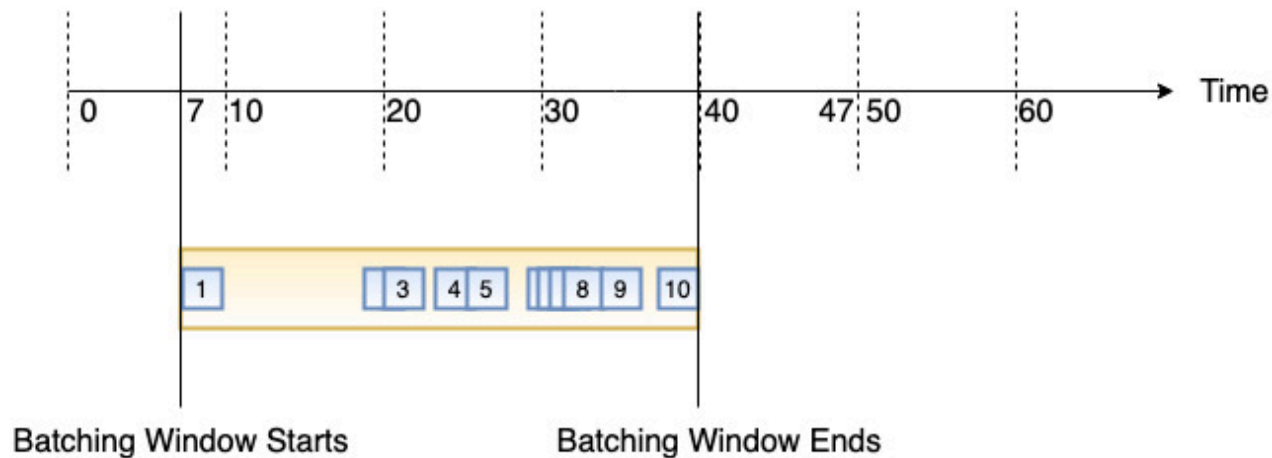

The following diagram illustrates these three conditions. Suppose a batching window begins at $t = 7$ seconds. In the first scenario, the batching window reaches its 40 second maximum at $t = 47$ seconds after accumulating 5 records. In the second scenario, the batch size reaches 10 before the batching window expires, so the batching window ends early. In the third scenario, the maximum payload size is reached before the batching window expires, so the batching window ends early.

Max Batching Window = 40 Seconds
Max Batch Size = 10
Max Batch Size in Bytes = 6 MB

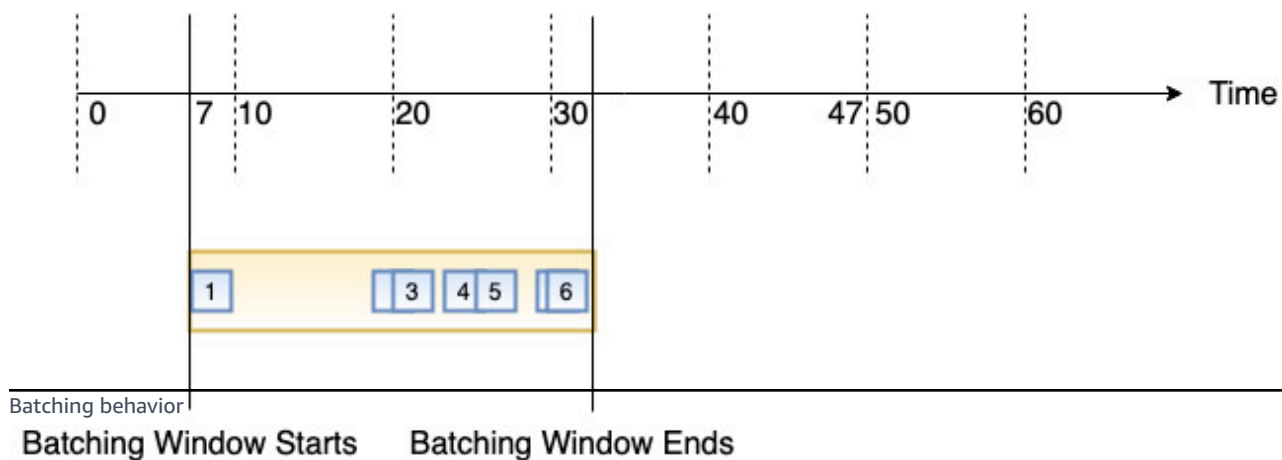

(1) Batching Window Expires

(2) Batching Size is reached

(3) Batch Size in bytes is reached

We recommend that you test with different batch and record sizes so that the polling frequency of each event source is tuned to how quickly your function is able to complete its task. The [CreateEventSourceMapping](#) `BatchSize` parameter controls the maximum number of records that can be sent to your function with each invoke. A larger batch size can often more efficiently absorb the invoke overhead across a larger set of records, increasing your throughput.

Lambda doesn't wait for any configured [extensions](#) to complete before sending the next batch for processing. In other words, your extensions may continue to run as Lambda processes the next batch of records. This can cause throttling issues if you breach any of your account's [concurrency](#) settings or limits. To detect whether this is a potential issue, monitor your functions and check whether you're seeing higher [concurrency metrics](#) than expected for your event source mapping. Due to short times in between invokes, Lambda may briefly report higher concurrency usage than the number of shards. This can be true even for Lambda functions without extensions.

By default, if your function returns an error, the event source mapping reprocesses the entire batch until the function succeeds, or the items in the batch expire. To ensure in-order processing, the event source mapping pauses processing for the affected shard until the error is resolved. For stream sources (DynamoDB and Kinesis), you can configure the maximum number of times that Lambda retries when your function returns an error. Service errors or throttles where the batch does not reach your function do not count toward retry attempts. You can also configure the event source mapping to send an invocation record to a [destination](#) when it discards an event batch.

Provisioned mode

Lambda event source mappings use event pollers to poll your event source for new messages. By default, Lambda manages the autoscaling of these pollers based on message volume. When message traffic increases, Lambda automatically increases the number of event pollers to handle the load, and reduces them when traffic decreases.

In provisioned mode, you can fine-tune the throughput of your event source mapping by defining minimum and maximum limits for dedicated polling resources that remain ready to handle expected traffic patterns. These resources auto-scale 3 times faster to handle sudden spikes in event traffic and provide 16 times higher capacity to process millions of events. This helps you build highly responsive event-driven workloads with stringent performance requirements.

In Lambda, an event poller is a compute unit with throughput capabilities that vary by event source type. For Amazon MSK and self-managed Apache Kafka, each event poller can handle up to 5 MB/sec of throughput or up to 5 concurrent invocations. For example, if your event source produces

an average payload of 1 MB and the average duration of your function is 1 second, a single Kafka event poller can support 5 MB/sec throughput and 5 concurrent Lambda invocations (assuming no payload transformation). For Amazon SQS, each event poller can handle up to 1 MB/sec of throughput or up to 10 concurrent invocations. Using provisioned mode incurs additional costs based on your event poller usage. For pricing details, see [AWS Lambda pricing](#).

Provisioned mode is available for Amazon MSK, self-managed Apache Kafka, and Amazon SQS event sources. While concurrency settings give you control over the scaling of your function, provisioned mode gives you control over the throughput of your event source mapping. To ensure maximum performance, you might need to adjust both settings independently.

Provisioned mode is ideal for real-time applications requiring consistent event processing latency, such as financial services firms processing market data feeds, e-commerce platforms providing real-time personalized recommendations, and gaming companies managing live player interactions.

Each event poller supports different throughput capacity:

- For Amazon MSK and self-managed Apache Kafka: up to 5 MB/sec of throughput or up to 5 concurrent invokes
- For Amazon SQS: up to 1 MB/sec of throughput or up to 10 concurrent invokes or up to 10 SQS polling API calls per second.

For Amazon SQS event source mappings, you can set the minimum number of pollers between 2 and 200 with a default of 2, and the maximum number between 2 and 2,000 with a default of 200. Lambda scales the number of event pollers between your configured minimum and maximum, quickly adding up to 1,000 concurrency per minute to provide consistent, low-latency processing of your events.

For Kafka event source mappings, you can set the minimum number of pollers between 1 and 200 with a default of 1, and the maximum number between 1 and 2,000 with a default of 200. Lambda scales the number of event pollers between your configured minimum and maximum based on your event backlog in your topic to provide low-latency processing of your events.

Note that for Amazon SQS event sources, the maximum concurrency setting cannot be used with provisioned mode. When using provisioned mode, you control concurrency through the maximum event pollers setting.

For details about configuring provisioned mode, see the following sections:

- [Configuring provisioned mode for Amazon MSK event source mappings](#)
- [Configuring provisioned mode for self-managed Apache Kafka event source mappings](#)
- [Using provisioned mode with Amazon SQS event source mappings](#)

To minimize latency in provisioned mode, set `MaximumBatchingWindowInSeconds` to 0. This setting ensures that Lambda will start processing the next batch immediately after completing the current function invocation. For additional information on low latency processing, see [Low latency Apache Kafka](#).

After configuring provisioned mode, you can observe the usage of event pollers for your workload by monitoring the `ProvisionedPollers` metric. For more information, see [the section called “Event source mapping metrics”](#).

Event source mapping API

To manage an event source with the [AWS Command Line Interface \(AWS CLI\)](#) or an [AWS SDK](#), you can use the following API operations:

- [CreateEventSourceMapping](#)
- [ListEventSourceMappings](#)
- [GetEventSourceMapping](#)
- [UpdateEventSourceMapping](#)
- [DeleteEventSourceMapping](#)

Using tags on event source mappings

You can tag event source mappings to organize and manage your resources. Tags are free-form key-value pairs associated with your resources that are supported across AWS services. For more information about use cases for tags, see [Common tagging strategies](#) in the *Tagging AWS Resources and Tag Editor Guide*.

Event source mappings are associated with functions, which can have their own tags. Event source mappings do not automatically inherit tags from functions. You can use the AWS Lambda API to view and update tags. You can also view and update tags while managing a specific event source mapping in the Lambda console, including those using Provisioned Mode for Amazon SQS.

Permissions required for working with tags

To allow an AWS Identity and Access Management (IAM) identity (user, group, or role) to read or set tags on a resource, grant it the corresponding permissions:

- **lambda:ListTags**—When a resource has tags, grant this permission to anyone who needs to call `ListTags` on it. For tagged functions, this permission is also necessary for `GetFunction`.
- **lambda:TagResource**—Grant this permission to anyone who needs to call `TagResource` or perform a tag on create.

Optionally, consider granting the **lambda:UntagResource** permission as well to allow `UntagResource` calls to the resource.

For more information, see [Identity-based IAM policies for Lambda](#).

Using tags with the Lambda console

You can use the Lambda console to create event source mappings that have tags, add tags to existing event source mappings, and filter event source mappings by tag, including those configured in Provisioned Mode for Amazon SQS.

When you add a trigger for supported stream and queue-based services using the Lambda console, Lambda automatically creates an event source mapping. For more information about these event sources, see [the section called “Event source mappings”](#). To create an event source mapping in the console, you will need the following prerequisites:

- A function.
- An event source from an affected service.

You can add the tags as part of the same user interface you use to create or update triggers.

To add a tag when you create a event source mapping

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function.
3. Under **Function overview**, choose **Add trigger**.
4. Under **Trigger configuration**, in the dropdown list, choose the name of the service your event source comes from.

5. Provide the core configuration for your event source. For more information about configuring your event source, consult the section for the related service in [Integrating other services](#).
6. Under **Event source mapping configuration**, choose **Additional settings**.
7. Under **Tags**, choose **Add new tag**
8. In the **Key** field, enter your tag key. For information about tagging restrictions, see [Tag naming limits and requirements](#) in the *Tagging AWS Resources and Tag Editor Guide*.
9. Choose **Add**.

To add tags to an existing event source mapping

1. Open [Event source mappings](#) in the Lambda console.
2. From the resource list, choose the **UUID** for the event source mapping corresponding to your **Function** and **Event source ARN**.
3. From the tab list below the **General configuration pane**, choose **Tags**.
4. Choose **Manage tags**.
5. Choose **Add new tag**.
6. In the **Key** field, enter your tag key. For information about tagging restrictions, see [Tag naming limits and requirements](#) in the *Tagging AWS Resources and Tag Editor Guide*.
7. Choose **Save**.

To filter event source mappings by tag

1. Open [Event source mappings](#) in the Lambda console.
2. Choose the search box.
3. From the dropdown list, select your tag key from below the **Tags** subheading.
4. Select **Use: "tag-name"** to see all event source mappings tagged with this key, or choose an **Operator** to further filter by value.
5. Select your tag value to filter by a combination of tag key and value.

The search box also supports searching for tag keys. Enter the name of a key to find it in the list.

Using tags with the AWS CLI

You can add and remove tags on existing Lambda resources, including event source mappings, with the Lambda API. You can also add tags when creating an event source mapping, which allows you to keep a resource tagged through its entire lifecycle.

Updating tags with the Lambda tag APIs

You can add and remove tags for supported Lambda resources through the [TagResource](#) and [UntagResource](#) API operations.

You can call these operations using the AWS CLI. To add tags to an existing resource, use the `tag-resource` command. This example adds two tags, one with the key *Department* and one with the key *CostCenter*.

```
aws lambda tag-resource \
--resource arn:aws:lambda:us-east-2:123456789012:resource-type:my-resource \
--tags Department=Marketing,CostCenter=1234ABCD
```

To remove tags, use the `untag-resource` command. This example removes the tag with the key *Department*.

```
aws lambda untag-resource --resource arn:aws:lambda:us-east-1:123456789012:resource-
type:resource-identifier \
--tag-keys Department
```

Adding tags when you create an event source mapping

To create a new Lambda event source mapping with tags, use the [CreateEventSourceMapping](#) API operation. Specify the `Tags` parameter. You can call this operation with the `create-event-source-mapping` AWS CLI command and the `--tags` option. For more information about the CLI command, see [create-event-source-mapping](#) in the *AWS CLI Command Reference*.

Before using the `Tags` parameter with `CreateEventSourceMapping`, ensure that your role has permission to tag resources alongside the usual permissions needed for this operation. For more information about permissions for tagging, see [the section called "Permissions required for working with tags"](#).

Viewing tags with the Lambda tag APIs

To view the tags that are applied to a specific Lambda resource, use the `ListTags` API operation. For more information, see [ListTags](#).

You can call this operation with the `list-tags` AWS CLI command by providing an ARN (Amazon Resource Name).

```
aws lambda list-tags --resource arn:aws:lambda:us-east-1:123456789012:resource-  
type:resource-identifier
```

Filtering resources by tag

You can use the AWS Resource Groups Tagging API [GetResources](#) API operation to filter your resources by tags. The `GetResources` operation receives up to 10 filters, with each filter containing a tag key and up to 10 tag values. You provide `GetResources` with a `ResourceType` to filter by specific resource types.

You can call this operation using the `get-resources` AWS CLI command. For examples of using `get-resources`, see [get-resources](#) in the *AWS CLI Command Reference*.

Control which events Lambda sends to your function

You can use event filtering to control which records from a stream or queue Lambda sends to your function. For example, you can add a filter so that your function only processes Amazon SQS messages containing certain data parameters. Event filtering works only with certain event source mappings. You can add filters to event source mappings for the following AWS services:

- Amazon DynamoDB
- Amazon Kinesis Data Streams
- Amazon MQ
- Amazon Managed Streaming for Apache Kafka (Amazon MSK)
- Self-managed Apache Kafka
- Amazon Simple Queue Service (Amazon SQS)

For specific information about filtering with specific event sources, see [the section called “Using filters with different AWS services”](#). Lambda doesn't support event filtering for Amazon DocumentDB.

By default, you can define up to five different filters for a single event source mapping. Your filters are logically ORed together. If a record from your event source satisfies one or more of your filters, Lambda includes the record in the next event it sends to your function. If none of your filters are satisfied, Lambda discards the record.

Note

If you need to define more than five filters for an event source, you can request a quota increase for up to 10 filters for each event source. If you attempt to add more filters than your current quota permits, Lambda will return an error when you try to create the event source.

Topics

- [Using filters with different AWS services](#)

Understanding event filtering basics

A filter criteria (`FilterCriteria`) object is a structure that consists of a list of filters (`Filters`). Each filter is a structure that defines an event filtering pattern (`Pattern`). A pattern is a string representation of a JSON filter rule. The structure of a `FilterCriteria` object is as follows.

```
{
  "Filters": [
    {
      "Pattern": "{ \"Metadata1\": [ rule1 ], \"data\": { \"Data1\": [ rule2 ] }}"
    }
  ]
}
```

For added clarity, here is the value of the filter's `Pattern` expanded in plain JSON.

```
{
  "Metadata1": [ rule1 ],
  "data": {
    "Data1": [ rule2 ]
  }
}
```

Your filter pattern can include metadata properties, data properties, or both. The available metadata parameters and the format of the data parameters vary according to the AWS service which is acting as the event source. For example, suppose your event source mapping receives the following record from an Amazon SQS queue:

```
{
  "messageId": "059f36b4-87a3-44ab-83d2-661975830a7d",
  "receiptHandle": "AQEBwJnKyrHigUMZj6rYigCgXlaS3SLy0a...",
}
```

```

    "body": "{\\n \\\"City\\\": \\\"Seattle\\\",\\n \\\"State\\\": \\\"WA\\\",\\n \\\"Temperature\\\": \\\"46\\\"}\\n}",
    "attributes": {
      "ApproximateReceiveCount": "1",
      "SentTimestamp": "1545082649183",
      "SenderId": "AIDAIENQZJOL023YVJ4V0",
      "ApproximateFirstReceiveTimestamp": "1545082649185"
    },
    "messageAttributes": {},
    "md5ofBody": "e4e68fb7bd0e697a0ae8f1bb342846b3",
    "eventSource": "aws:sqs",
    "eventSourceARN": "arn:aws:sqs:us-east-2:123456789012:my-queue",
    "awsRegion": "us-east-2"
  }
}

```

- **Metadata properties** are the fields containing information about the event that created the record. In the example Amazon SQS record, the metadata properties include fields such as `messageID`, `eventSourceArn`, and `awsRegion`.
- **Data properties** are the fields of the record containing the data from your stream or queue. In the Amazon SQS event example, the key for the data field is `body`, and the data properties are the fields `City`, `State`, and `Temperature`.

Different types of event source use different key values for their data fields. To filter on data properties, make sure that you use the correct key in your filter's pattern. For a list of data filtering keys, and to see examples of filter patterns for each supported AWS service, refer to [Using filters with different AWS services](#).

Event filtering can handle multi-level JSON filtering. For example, consider the following fragment of a record from a DynamoDB stream:

```

"dynamodb": {
  "Keys": {
    "ID": {
      "S": "ABCD"
    }
    "Number": {
      "N": "1234"
    }
  },
  ...
}

```

Suppose you want to process only those records where the value of the sort key `Number` is 4567. In this case, your `FilterCriteria` object would look like this:

```
{
  "Filters": [
    {
      "Pattern": "{ \"dynamodb\": { \"Keys\": { \"Number\": { \"N\": [ \"4567\" ] } } } }"
    }
  ]
}
```

For added clarity, here is the value of the filter's `Pattern` expanded in plain JSON.

```
{
  "dynamodb": {
    "Keys": {
      "Number": {
        "N": [ "4567" ]
      }
    }
  }
}
```

Handling records that don't meet filter criteria

How Lambda handles records that don't meet your filter criteria depends on the event source.

- For **Amazon SQS**, if a message doesn't satisfy your filter criteria, Lambda automatically removes the message from the queue. You don't have to manually delete these messages in Amazon SQS.
- For **Kinesis** and **DynamoDB**, after your filter criteria evaluates a record, the streams iterator advances past this record. If the record doesn't satisfy your filter criteria, you don't have to manually delete the record from your event source. After the retention period, Kinesis and DynamoDB automatically delete these old records. If you want records to be deleted sooner, see [Changing the Data Retention Period](#).
- For **Amazon MSK**, **self-managed Apache Kafka**, and **Amazon MQ** messages, Lambda drops messages that don't match all fields included in the filter. For Amazon MSK and self-managed Apache Kafka, Lambda commits offsets for matched and unmatched messages after successfully invoking the function. For Amazon MQ, Lambda acknowledges matched messages after successfully invoking the function, and acknowledges unmatched messages when filtering them.

Filter rule syntax

For filter rules, Lambda supports the Amazon EventBridge rules and uses the same syntax as EventBridge. For more information, see [Amazon EventBridge event patterns](#) in the *Amazon EventBridge User Guide*.

The following is a summary of all the comparison operators available for Lambda event filtering.

Comparison operator	Example	Rule syntax
Null	UserID is null	"UserID": [null]
Empty	LastName is empty	"LastName": [""]
Equals	Name is "Alice"	"Name": ["Alice"]
Equals (ignore case)	Name is "Alice"	"Name": [{ "equals-ignore-case": "alice" }]
And	Location is "New York" and Day is "Monday"	"Location": ["New York"], "Day": ["Monday"]
Or	PaymentType is "Credit" or "Debit"	"PaymentType": ["Credit", "Debit"]
Or (multiple fields)	Location is "New York", or Day is "Monday".	"\$or": [{ "Location": ["New York"] }, { "Day": ["Monday"] }]
Not	Weather is anything but "Raining"	"Weather": [{ "anything-but": ["Raining"] }]
Numeric (equals)	Price is 100	"Price": [{ "numeric": ["=", 100] }]
Numeric (range)	Price is more than 10, and less than or equal to 20	"Price": [{ "numeric": [">", 10, "<=", 20] }]
Exists	ProductName exists	"ProductName": [{ "exists": true }]

Comparison operator	Example	Rule syntax
Does not exist	ProductName does not exist	"ProductName": [{ "exists": false }]
Begins with	Region is in the US	"Region": [{"prefix": "us-" }]
Ends with	FileName ends with a .png extension.	"FileName": [{ "suffix": ".png" }]

Note

Like EventBridge, for strings, Lambda uses exact character-by-character matching without case-folding or any other string normalization. For numbers, Lambda also uses string representation. For example, 300, 300.0, and 3.0e2 are not considered equal.

Note that the Exists operator only works on leaf nodes in your event source JSON. It doesn't match intermediate nodes. For example, with the following JSON, the filter pattern `{ "person": { "address": [{ "exists": true }] } }` wouldn't find a match because "address" is an intermediate node.

```
{
  "person": {
    "name": "John Doe",
    "age": 30,
    "address": {
      "street": "123 Main St",
      "city": "Anytown",
      "country": "USA"
    }
  }
}
```

Attaching filter criteria to an event source mapping (console)

Follow these steps to create a new event source mapping with filter criteria using the Lambda console.

To create a new event source mapping with filter criteria (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of a function to create an event source mapping for.
3. Under **Function overview**, choose **Add trigger**.
4. For **Trigger configuration**, choose a trigger type that supports event filtering. For a list of supported services, refer to the list at the beginning of this page.
5. Expand **Additional settings**.
6. Under **Filter criteria**, choose **Add**, and then define and enter your filters. For example, you can enter the following.

```
{ "Metadata" : [ 1, 2 ] }
```

This instructs Lambda to process only the records where field Metadata is equal to 1 or 2. You can continue to select **Add** to add more filters up to the maximum allowed amount.

7. When you have finished adding your filters, choose **Save**.

When you enter filter criteria using the console, you enter only the filter pattern and don't need to provide the Pattern key or escape quotes. In step 6 of the preceding instructions, { "Metadata" : [1, 2] } corresponds to the following FilterCriteria.

```
{
  "Filters": [
    {
      "Pattern": "{ \"Metadata\" : [ 1, 2 ] }"
    }
  ]
}
```

After creating your event source mapping in the console, you can see the formatted FilterCriteria in the trigger details. For more examples of creating event filters using the console, see [Using filters with different AWS services](#).

Attaching filter criteria to an event source mapping (AWS CLI)

Suppose you want an event source mapping to have the following FilterCriteria:

```
{
  "Filters": [
    {
      "Pattern": "{ \"Metadata\" : [ 1, 2 ] }"
    }
  ]
}
```

To create a new event source mapping with these filter criteria using the AWS Command Line Interface (AWS CLI), run the following command.

```
aws lambda create-event-source-mapping \
  --function-name my-function \
  --event-source-arn arn:aws:sqs:us-east-2:123456789012:my-queue \
  --filter-criteria '{"Filters": [{"Pattern": "{ \"Metadata\" : [ 1, 2 ] }"}]}'
```

This [create-event-source-mapping](#) command creates a new Amazon SQS event source mapping for function *my-function* with the specified `FilterCriteria`.

To add these filter criteria to an existing event source mapping, run the following command.

```
aws lambda update-event-source-mapping \
  --uuid "a1b2c3d4-5678-90ab-cdef-11111EXAMPLE" \
  --filter-criteria '{"Filters": [{"Pattern": "{ \"Metadata\" : [ 1, 2 ] }"}]}'
```

Note that to update an event source mapping, you need its UUID. You can get the UUID from a [list-event-source-mappings](#) call. Lambda also returns the UUID in the [create-event-source-mapping](#) CLI response.

To remove filter criteria from an event source, you can run the following [update-event-source-mapping](#) command with an empty `FilterCriteria` object.

```
aws lambda update-event-source-mapping \
  --uuid "a1b2c3d4-5678-90ab-cdef-11111EXAMPLE" \
  --filter-criteria "{}"
```

For more examples of creating event filters using the AWS CLI, see [Using filters with different AWS services](#).

Attaching filter criteria to an event source mapping (AWS SAM)

Suppose you want to configure an event source in AWS SAM to use the following filter criteria:

```
{
  "Filters": [
    {
      "Pattern": "{ \"Metadata\" : [ 1, 2 ] }"
    }
  ]
}
```

To add these filter criteria to your event source mapping, insert the following snippet into the YAML template for your event source.

```
FilterCriteria:
  Filters:
    - Pattern: '{"Metadata": [1, 2]}'
```

For more information on creating and configuring an AWS SAM template for an event source mapping, see the [EventSource](#) section of the AWS SAM Developer Guide. For more examples of creating event filters using AWS SAM templates, see [Using filters with different AWS services](#).

Encryption of filter criteria

By default, Lambda doesn't encrypt your filter criteria object. For use cases where you may include sensitive information in your filter criteria object, you can use your own [KMS key](#) to encrypt it.

After you encrypt your filter criteria object, you can view its plaintext version using a [GetEventSourceMapping](#) API call. You must have `kms:Decrypt` permissions to be able to successfully view the filter criteria in plaintext.

Note

If your filter criteria object is encrypted, Lambda redacts the value of the `FilterCriteria` field in the response of [ListEventSourceMappings](#) calls. Instead, this field displays as `null`. To see the true value of `FilterCriteria`, use the [GetEventSourceMapping](#) API. To view the decrypted value of `FilterCriteria` in the console, ensure that your IAM role contains permissions for [GetEventSourceMapping](#).

You can specify your own KMS key via the console, API/CLI, or CloudFormation.

To encrypt filter criteria with a customer-owned KMS key (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Add trigger**. If you already have an existing trigger, choose the **Configuration** tab, and then choose **Triggers**. Select the existing trigger, and choose **Edit**.
3. Select the checkbox next to **Encrypt with customer managed KMS key**.
4. For **Choose a customer managed KMS encryption key**, select an existing enabled key or create a new key. Depending on the operation, you need some or all of the following permissions: `kms:DescribeKey`, `kms:GenerateDataKey`, and `kms:Decrypt`. Use the KMS key policy to grant these permissions.

If you use your own KMS key, the following API operations must be permitted in the [key policy](#):

- `kms:Decrypt` – Must be granted to the regional Lambda service principal (`lambda.AWS_region.amazonaws.com`). This allows Lambda to decrypt data with this KMS key.
- To prevent a [cross-service confused deputy problem](#), the key policy uses the `aws:SourceArn` global condition key. The correct value of the `aws:SourceArn` key is the ARN of your event source mapping resource, so you can add this to your policy only after you know its ARN. Lambda also forwards the `aws:lambda:FunctionArn` and `aws:lambda:EventSourceArn` keys and their respective values in the [encryption context](#) when making a decryption request to KMS. These values must match the specified conditions in the key policy for the decryption request to succeed. You don't need to include `EventSourceArn` for Self-managed Kafka event sources since they don't have an `EventSourceArn`.
- `kms:Decrypt` – Must also be granted to the principal that intends to use the key to view the plaintext filter criteria in [GetEventSourceMapping](#) or [DeleteEventSourceMapping](#) API calls.
- `kms:DescribeKey` – Provides the customer managed key details to allow the specified principal to use the key.
- `kms:GenerateDataKey` – Provides permissions for Lambda to generate a data key to encrypt the filter criteria, on behalf of the specified principal ([envelope encryption](#)).

You can use AWS CloudTrail to track AWS KMS requests that Lambda makes on your behalf. For sample CloudTrail events, see [???](#).

We also recommend using the [kms:ViaService](#) condition key to limit the use of the KMS key to requests from Lambda only. The value of this key is the regional Lambda service principal (`lambda.AWS_region.amazonaws.com`). The following is a sample key policy that grants all the relevant permissions:

Example AWS KMS key policy

JSON

```
{
  "Version": "2012-10-17",
  "Id": "example-key-policy-1",
  "Statement": [
    {
      "Sid": "Allow Lambda to decrypt using the key",
      "Effect": "Allow",
      "Principal": {
        "Service": "lambda.us-east-1.amazonaws.com"
      },
      "Action": [
        "kms:Decrypt"
      ],
      "Resource": "*",
      "Condition": {
        "ArnEquals": {
          "aws:SourceArn": [
            "arn:aws:lambda:us-east-1:123456789012:event-source-
mapping:<esm_uuid>"
          ]
        },
        "StringEquals": {
          "kms:EncryptionContext:aws:lambda:FunctionArn": "arn:aws:lambda:us-
east-1:123456789012:function:test-function",
          "kms:EncryptionContext:aws:lambda:EventSourceArn": "arn:aws:sqs:us-
east-1:123456789012:test-queue"
        }
      }
    },
    {
      "Sid": "Allow actions by an AWS account on the key",
```

```

        "Effect": "Allow",
        "Principal": {
            "AWS": "arn:aws:iam::123456789012:root"
        },
        "Action": "kms:*",
        "Resource": "*"
    },
    {
        "Sid": "Allow use of the key to specific roles",
        "Effect": "Allow",
        "Principal": {
            "AWS": "arn:aws:iam::123456789012:role/ExampleRole"
        },
        "Action": [
            "kms:Decrypt",
            "kms:DescribeKey",
            "kms:GenerateDataKey"
        ],
        "Resource": "*",
        "Condition": {
            "StringEquals" : {
                "kms:ViaService": "lambda.us-east-1.amazonaws.com"
            }
        }
    }
]
}

```

To use your own KMS key to encrypt filter criteria, you can also use the following [CreateEventSourceMapping](#) AWS CLI command. Specify the KMS key ARN with the `--kms-key-arn` flag.

```

aws lambda create-event-source-mapping --function-name my-function \
  --maximum-batching-window-in-seconds 60 \
  --event-source-arn arn:aws:sqs:us-east-1:123456789012:my-queue \
  --filter-criteria "{\"filters\": [{\"pattern\": \"{\\\"a\\\": [\\\"1\\\", \\\"2\\\"]}\" }]}\" \
  --kms-key-arn arn:aws:kms:us-east-1:123456789012:key/055efbb4-xmpl-4336-
ba9c-538c7d31f599

```

If you have an existing event source mapping, use the [UpdateEventSourceMapping](#) AWS CLI command instead. Specify the KMS key ARN with the `--kms-key-arn` flag.

```
aws lambda update-event-source-mapping --function-name my-function \
  --maximum-batching-window-in-seconds 60 \
  --event-source-arn arn:aws:sqs:us-east-1:123456789012:my-queue \
  --filter-criteria '{"filters": [{"pattern": "{\"a\": [1, 2]}"}]}' \
  --kms-key-arn arn:aws:kms:us-east-1:123456789012:key/055efbb4-xmpl-4336-  
ba9c-538c7d31f599
```

This operation overwrites any KMS key that was previously specified. If you specify the `--kms-key-arn` flag along with an empty argument, Lambda stops using your KMS key to encrypt filter criteria. Instead, Lambda defaults back to using an Amazon-owned key.

To specify your own KMS key in a CloudFormation template, use the `KMSKeyArn` property of the `AWS::Lambda::EventSourceMapping` resource type. For example, you can insert the following snippet into the YAML template for your event source.

```
MyEventSourceMapping:
  Type: AWS::Lambda::EventSourceMapping
  Properties:
    ...
    FilterCriteria:
      Filters:
        - Pattern: '{"a": [1, 2]}'
      KMSKeyArn: "arn:aws:kms:us-east-1:123456789012:key/055efbb4-xmpl-4336-  
ba9c-538c7d31f599"
    ...
```

To be able to view your encrypted filter criteria in plaintext in a [GetEventSourceMapping](#) or [DeleteEventSourceMapping](#) API call, you must have `kms:Decrypt` permissions.

Starting August 6, 2024, the `FilterCriteria` field no longer shows up in AWS CloudTrail logs from [CreateEventSourceMapping](#), [UpdateEventSourceMapping](#), and [DeleteEventSourceMapping](#) API calls if your function doesn't use event filtering. If your function does use event filtering, the `FilterCriteria` field shows up as empty (`{}`). You can still view your filter criteria in plaintext in the response of [GetEventSourceMapping](#) API calls if you have `kms:Decrypt` permissions for the correct KMS key.

Sample CloudTrail log entry for Create/Update/DeleteEventSourceMapping calls

In the following AWS CloudTrail sample log entry for a `CreateEventSourceMapping` call, `FilterCriteria` shows up as empty (`{}`) because the function uses event filtering. This is the

case even if `FilterCriteria` object contains valid filter criteria that your function is actively using. If the function doesn't use event filtering, CloudTrail won't display the `FilterCriteria` field at all in log entries.

Using filters with different AWS services

Different types of event source use different key values for their data fields. To filter on data properties, make sure that you use the correct key in your filter's pattern. The following table gives the filtering keys for each supported AWS service.

AWS service	Filtering key
DynamoDB	dynamodb
Kinesis	data

AWS service	Filtering key
Amazon MQ	data
Amazon MSK	value
Self-managed Apache Kafka	value
Amazon SQS	body

The following sections give examples of filter patterns for different types of event sources. They also provide definitions of supported incoming data formats and filter pattern body formats for each supported service.

- [the section called “Event filtering”](#)
- [the section called “Event filtering”](#)
- [the section called “Event filtering”](#)
- [the section called “Event filtering”](#)
- [the section called “Event filtering”](#)

Testing Lambda functions in the console

You can test your Lambda function in the console by invoking your function with a test event. A *test event* is a JSON input to your function. If your function doesn't require input, the event can be an empty document (`{}`).

When you run a test in the console, Lambda synchronously invokes your function with the test event. The function runtime converts the event JSON into an object and passes it to your code's handler method for processing.

Create a test event

Before you can test in the console, you need to create a private or shareable test event.

Invoking functions with test events

To test a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to test.
3. Choose the **Test** tab.
4. Under **Test event**, choose **Create new event** or **Edit saved event** and then choose the saved event that you want to use.
5. Optionally - choose a **Template** for the event JSON.
6. Choose **Test**.
7. To review the test results, under **Execution result**, expand **Details**.

To invoke your function without saving your test event, choose **Test** before saving. This creates an unsaved test event that Lambda preserves only for the duration of the session.

For the Node.js, Python, and Ruby runtimes, you can also access your existing saved and unsaved test events on the **Code** tab. Use the **TEST EVENTS** section to create, edit, and run tests.

Creating private test events

Private test events are available only to the event creator, and they require no additional permissions to use. You can create and save up to 10 private test events per function.

To create a private test event

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to test.
3. Choose the **Test** tab.
4. Under **Test event**, do the following:
 - a. Choose a **Template**.
 - b. Enter a **Name** for the test.
 - c. In the text entry box, enter the JSON test event.
 - d. Under **Event sharing settings**, choose **Private**.
5. Choose **Save changes**.

For the Node.js, Python, and Ruby runtimes, you can also create test events on the **Code** tab. Use the **TEST EVENTS** section to create, edit, and run tests.

Creating shareable test events

Shareable test events are test events that you can share with other users in the same AWS account. You can edit other users' shareable test events and invoke your function with them.

Lambda saves shareable test events as schemas in an [Amazon EventBridge \(CloudWatch Events\) schema registry](#) named `lambda-testevent-schemas`. As Lambda utilizes this registry to store and call shareable test events you create, we recommend that you do not edit this registry or create a registry using the `lambda-testevent-schemas` name.

To see, share, and edit shareable test events, you must have permissions for all of the following [EventBridge \(CloudWatch Events\) schema registry API operations](#):

- [schemas.CreateRegistry](#)
- [schemas.CreateSchema](#)
- [schemas.DeleteSchema](#)

- [schemas.DeleteSchemaVersion](#)
- [schemas.DescribeRegistry](#)
- [schemas.DescribeSchema](#)
- [schemas.GetDiscoveredSchema](#)
- [schemas.ListSchemaVersions](#)
- [schemas.UpdateSchema](#)

Note that saving edits made to a shareable test event overwrites that event.

If you cannot create, edit, or see shareable test events, check that your account has the required permissions for these operations. If you have the required permissions but still cannot access shareable test events, check for any [resource-based policies](#) that might limit access to the EventBridge (CloudWatch Events) registry.

To create a shareable test event

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to test.
3. Choose the **Test** tab.
4. Under **Test event**, do the following:
 - a. Choose a **Template**.
 - b. Enter a **Name** for the test.
 - c. In the text entry box, enter the JSON test event.
 - d. Under **Event sharing settings**, choose **Shareable**.
5. Choose **Save changes**.

Use shareable test events with AWS Serverless Application Model.

You can use AWS SAM to invoke shareable test events. See [sam remote test-event](#) in the [AWS Serverless Application Model Developer Guide](#)

Deleting shareable test event schemas

When you delete shareable test events, Lambda removes them from the `lambda-testevent-schemas` registry. If you remove the last shareable test event from the registry, Lambda deletes the registry.

If you delete the function, Lambda does not delete any associated shareable test event schemas. You must clean up these resources manually from the [EventBridge \(CloudWatch Events\) console](#).

Lambda function states

Lambda includes a [State](#) field in the function configuration for all functions to indicate when your function is ready to invoke. State provides information about the current status of the function, including whether you can successfully invoke the function. Function states do not change the behavior of function invocations or how your function runs the code.

Note

Function state definitions differ slightly for [SnapStart](#) functions. For more information, see [Lambda SnapStart and function states](#).

In many cases, a DynamoDB table is an ideal way to retain state between invocations since it provides low-latency data access and can scale with the Lambda service. You can also store data in [Amazon EFS for Lambda](#) if you are using this service, and this provides low-latency access to file system storage.

Function states include:

- **Pending** – After Lambda creates the function, it sets the state to pending. While in pending state, Lambda attempts to create or configure resources for the function, such as VPC or EFS resources. Lambda does not invoke a function during pending state. Any invocations or other API actions that operate on the function will fail.
- **Active** – Your function transitions to active state after Lambda completes resource configuration and provisioning. Functions can only be successfully invoked while active.
- **Failed** – Indicates that resource configuration or provisioning encountered an error. When function creation fails, Lambda sets the function state to failed, and you must delete and recreate the function.
- **Inactive** – A function becomes inactive when it has been idle long enough for Lambda to reclaim the external resources that were configured for it. When you try to invoke a function that is inactive, the invocation fails and Lambda sets the function to pending state until the function resources are recreated. If Lambda fails to recreate the resources, the function returns to the inactive state. You might need to resolve any errors and redeploy your function to restore it to the active state.

If you are using SDK-based automation workflows or calling Lambda's service APIs directly, ensure that you check a function's state before invocation to verify that it is active. You can do this with the Lambda API action [GetFunction](#), or by configuring a waiter using the [AWS SDK for Java 2.0](#).

```
aws lambda get-function --function-name my-function --query 'Configuration.[State, LastUpdateStatus]'
```

You should see the following output:

```
[  
  "Active",  
  "Successful"  
]
```

The following operations fail while function creation is pending:

- [Invoke](#)
- [UpdateFunctionCode](#)
- [UpdateFunctionConfiguration](#)
- [PublishVersion](#)

Function states during updates

Lambda has two operations for updating functions:

- [UpdateFunctionCode](#): Updates the function's deployment package
- [UpdateFunctionConfiguration](#): Updates the function's configuration

Lambda uses the [LastUpdateStatus](#) attribute to track the progress of these update operations. While an update is in progress (when "LastUpdateStatus": "InProgress"):

- The function's [State](#) remains `Active`.
- Invocations continue to use the function's previous code and configuration until the update completes.
- The following operations fail:
 - [UpdateFunctionCode](#)

- [UpdateFunctionConfiguration](#)
- [PublishVersion](#)
- [TagResource](#)

When an update fails (when "LastUpdateStatus": "Failed"):

- The function's [State](#) remains Active.
- Invocations continue to use the function's previous code and configuration.

Example GetFunctionConfiguration response

The following example is the result of [GetFunctionConfiguration](#) request on a function undergoing an update.

```
{
  "FunctionName": "my-function",
  "FunctionArn": "arn:aws:lambda:us-east-1:123456789012:function:my-function",
  "Runtime": "nodejs24.x",
  "VpcConfig": {
    "SubnetIds": [
      "subnet-071f712345678e7c8",
      "subnet-07fd123456788a036",
      "subnet-0804f77612345cacf"
    ],
    "SecurityGroupIds": [
      "sg-085912345678492fb"
    ],
    "VpcId": "vpc-08e1234569e011e83"
  },
  "State": "Active",
  "LastUpdateStatus": "InProgress",
  ...
}
```

Understanding retry behavior in Lambda

When you invoke a function directly, you determine the strategy for handling errors related to your function code. Lambda does not automatically retry these types of errors on your behalf. To retry, you can manually re-invoke your function, send the failed event to a queue for debugging, or ignore the error. Your function's code might have run completely, partially, or not at all. If you retry, ensure that your function's code can handle the same event multiple times without causing duplicate transactions or other unwanted side effects.

When you invoke a function indirectly, you need to be aware of the retry behavior of the invoker and any service that the request encounters along the way. This includes the following scenarios.

- **Asynchronous invocation** – Lambda retries function errors twice. If the function doesn't have enough capacity to handle all incoming requests, events might wait in the queue for hours to be sent to the function. You can configure a dead-letter queue on the function to capture events that weren't successfully processed. For more information, see [the section called “Dead-letter queues”](#).
- **Event source mappings** – Event source mappings that read from streams retry the entire batch of items. Repeated errors block processing of the affected shard until the error is resolved or the items expire. To detect stalled shards, you can monitor the [Iterator Age](#) metric.

For event source mappings that read from a queue, you determine the length of time between retries and destination for failed events by configuring the visibility timeout and redrive policy on the source queue. For more information, see [How Lambda processes records from stream and queue-based event sources](#) and the service-specific topics under [Invoking Lambda with events from other AWS services](#).

- **AWS services** – AWS services can invoke your function [synchronously](#) or asynchronously. For synchronous invocation, the service decides whether to retry. For example, Amazon S3 batch operations retries the operation if the Lambda function returns a `TemporaryFailure` response code. Services that proxy requests from an upstream user or client may have a retry strategy or may relay the error response back to the requester. For example, API Gateway always relays the error response back to the requester.

For asynchronous invocation, the retry logic is the same regardless of the invocation source. By default, Lambda retries a failed asynchronous invocation up to two times. For more information, see [How Lambda handles errors and retries with asynchronous invocation](#).

- **Other accounts and clients** – When you grant access to other accounts, you can use [resource-based policies](#) to restrict the services or resources they can configure to invoke your function. To protect your function from being overloaded, consider putting an API layer in front of your function with [Amazon API Gateway](#).

To help you deal with errors in Lambda applications, Lambda integrates with services like Amazon CloudWatch and AWS X-Ray. You can use a combination of logs, metrics, alarms, and tracing to quickly detect and identify issues in your function code, API, or other resources that support your application. For more information, see [Monitoring, debugging, and troubleshooting Lambda functions](#).

Use Lambda recursive loop detection to prevent infinite loops

When you configure a Lambda function to output to the same service or resource that invokes the function, it's possible to create an infinite recursive loop. For example, a Lambda function might write a message to an Amazon Simple Queue Service (Amazon SQS) queue, which then invokes the same function. This invocation causes the function to write another message to the queue, which in turn invokes the function again.

Unintentional recursive loops can result in unexpected charges being billed to your AWS account. Loops can also cause Lambda to [scale](#) and use all of your account's available concurrency. To help reduce the impact of unintentional loops, Lambda detects certain types of recursive loops shortly after they occur. By default, when Lambda detects a recursive loop, it stops your function being invoked and notifies you. If your design intentionally uses recursive patterns, you can change a function's default configuration to allow it to be invoked recursively. See [the section called "Allowing a Lambda function to run in a recursive loop"](#) for more information.

Sections

- [Understanding recursive loop detection](#)
- [Supported AWS services and SDKs](#)
- [Recursive loop notifications](#)
- [Responding to recursive loop detection notifications](#)
- [Allowing a Lambda function to run in a recursive loop](#)
- [Supported Regions for Lambda recursive loop detection](#)

Understanding recursive loop detection

Recursive loop detection in Lambda works by tracking events. Lambda is an event-driven compute service that runs your function code when certain events occur. For example, when an item is added to an Amazon SQS queue or Amazon Simple Notification Service (Amazon SNS) topic. Lambda passes events to your function as JSON objects, which contain information about the change in the system state. When an event causes your function to run, this is called an *invocation*.

To detect recursive loops, Lambda uses [AWS X-Ray](#) tracing headers. When [AWS services that support recursive loop detection](#) send events to Lambda, those events are automatically annotated with metadata. When your Lambda function writes one of these events to another supported AWS

service using a [supported version of an AWS SDK](#), it updates this metadata. The updated metadata includes a count of the number of times that the event has invoked the function.

 **Note**

You don't need to enable X-Ray active tracing for this feature to work. Recursive loop detection is turned on by default for all AWS customers. There is no charge to use the feature.

A *chain of requests* is a sequence of Lambda invocations caused by the same triggering event. For example, imagine that an Amazon SQS queue invokes your Lambda function. Your Lambda function then sends the processed event back to the same Amazon SQS queue, which invokes your function again. In this example, each invocation of your function falls in the same chain of requests.

If your function is invoked approximately 16 times in the same chain of requests, then Lambda automatically stops the next function invocation in that request chain and notifies you. If your function is configured with multiple triggers, then invocations from other triggers aren't affected.

 **Note**

Even when the `maxReceiveCount` setting on the source queue's redrive policy is higher than 16, Lambda recursion protection does not prevent Amazon SQS from retrying the message after a recursive loop is detected and terminated. When Lambda detects a recursive loop and drops subsequent invocations, it returns a `RecursiveInvocationException` to the event source mapping. This increments the `receiveCount` value on the message. Lambda continues to retry the message, and continues to block function invocations, until Amazon SQS determines that the `maxReceiveCount` is exceeded and sends the message to the configured dead-letter queue.

If you have an [on-failure destination](#) or [dead-letter queue](#) configured for your function, then Lambda also sends the event from the stopped invocation to your destination or dead-letter queue. When configuring a destination or dead-letter queue for your function, be sure not to use an event trigger or event source mapping that your function also uses. If you send events to the

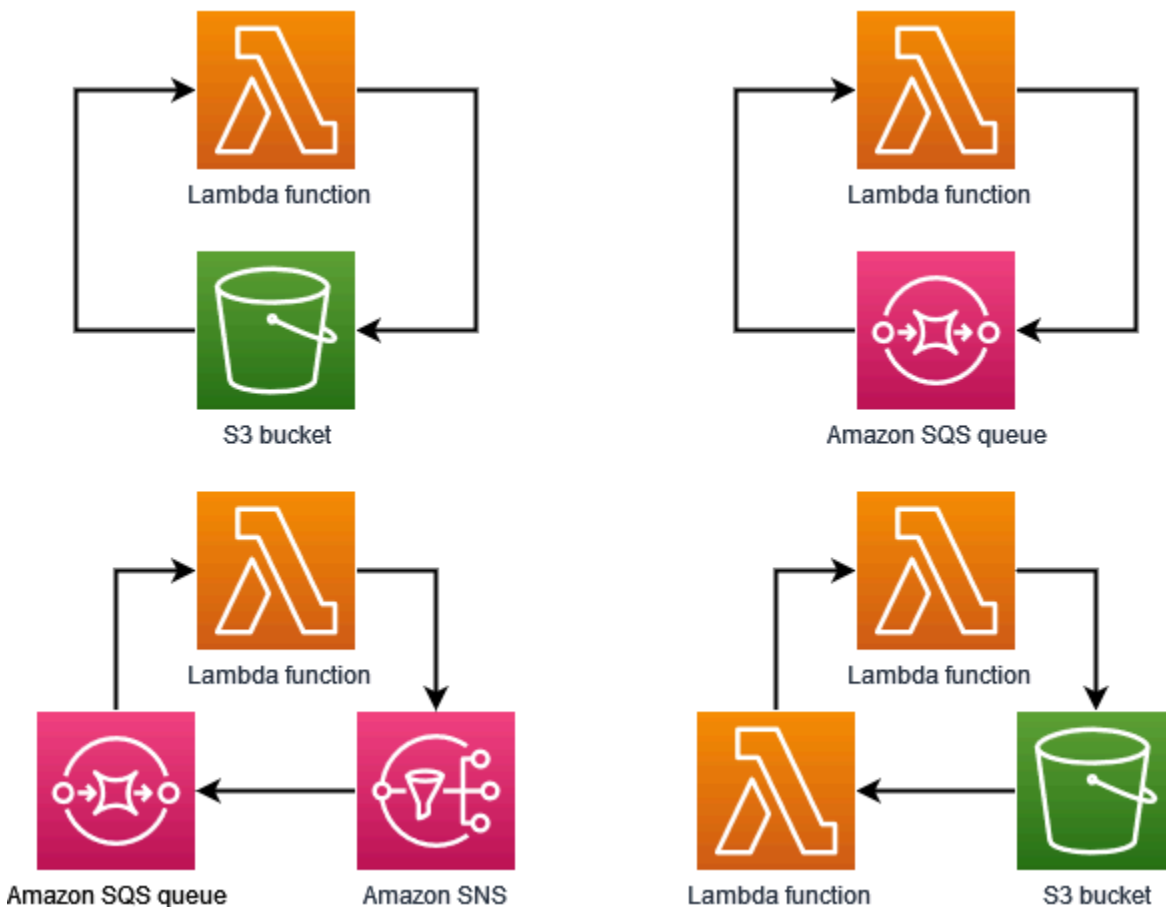

same resource that invokes your function, then you can create another recursive loop and this loop will also be terminated. If you opt out of recursion loop detection, this loop will not be terminated.

Supported AWS services and SDKs

Lambda can detect only recursive loops that include certain supported AWS services. For recursive loops to be detected, your function must also use one of the supported AWS SDKs.

Supported AWS services

Lambda currently detects recursive loops between your functions, Amazon SQS, Amazon S3, and Amazon SNS. Lambda also detects loops comprised only of Lambda functions, which may invoke each other synchronously or asynchronously. The following diagrams show some examples of loops that Lambda can detect:

When another AWS service such as Amazon DynamoDB forms part of the loop, Lambda can't currently detect and stop it.

Because Lambda currently detects only recursive loops involving Amazon SQS, Amazon S3, and Amazon SNS, it's still possible that loops involving other AWS services can result in unintended usage of your Lambda functions.

To guard against unexpected charges being billed to your AWS account, we recommend that you configure [Amazon CloudWatch alarms](#) to alert you to unusual usage patterns. For example, you can configure CloudWatch to notify you about spikes in Lambda function concurrency or invocations. You can also configure a [billing alarm](#) to notify you when spending in your account exceeds a threshold that you specify. Or, you can use [AWS Cost Anomaly Detection](#) to alert you to unusual billing patterns.

Supported AWS SDKs

For Lambda to detect recursive loops, your function must use one of the following SDK versions or higher:

Runtime	Minimum required AWS SDK version
Node.js	2.1147.0 (SDK version 2)
	3.105.0 (SDK version 3)
Python	1.24.46 (boto3)
	1.27.46 (botocore)
Java 8 and Java 11	2.17.135
Java 17	2.20.81
Java 21	2.21.24
.NET	3.7.293.0
Ruby	3.134.0
PHP	3.232.0
Go	V2 SDK 1.57.0

Some Lambda runtimes such as Python and Node.js include a version of the AWS SDK. If the SDK version included in your function's runtime is lower than the minimum required, then you can add a supported version of the SDK to your function's deployment package. You can also add a supported SDK version to your function using a [Lambda layer](#). For a list of the SDKs included with each Lambda runtime, see [Lambda runtimes](#).

Recursive loop notifications

When Lambda stops a recursive loop, you receive notifications through the [Health Dashboard](#) and through email. You can also use CloudWatch metrics to monitor the number of recursive invocations that Lambda has stopped.

Health Dashboard notifications

When Lambda stops a recursive invocation, the Health Dashboard displays a notification on the **Your account health** page, under [Open and recent issues](#). Note that it can take up to 3.5 hours after Lambda stops a recursive invocation before this notification is displayed. For more information about viewing account events in the Health Dashboard, see [Getting started with your AWS Health Dashboard – Your account health](#) in the *AWS Health User Guide*.

Email alerts

When Lambda first stops a recursive invocation of your function, it sends you an email alert. Lambda sends a maximum of one email every 24 hours for each function in your AWS account. After Lambda sends an email notification, you won't receive any more emails for that function for another 24 hours, even if Lambda stops further recursive invocations of the function. Note that it can take up to 3.5 hours after Lambda stops a recursive invocation before you receive this email alert.

Lambda sends recursive loop email alerts to your AWS account's primary account contact and alternate operations contact. For information about viewing or updating the email addresses in your account, see [Updating contact information](#) in the *AWS General Reference*.

Amazon CloudWatch metrics

The [CloudWatch metric](#) `RecursiveInvocationsDropped` records the number of function invocations that Lambda has stopped because your function has been invoked more than approximately 16 times in a single chain of requests. Lambda emits this metric as soon as it stops a recursive invocation. To view this metric, follow the instructions for [Viewing metrics on the CloudWatch console](#) and choose the metric `RecursiveInvocationsDropped`.

Responding to recursive loop detection notifications

When your function is invoked more than approximately 16 times by the same triggering event, Lambda stops the next function invocation for that event to break the recursive loop. To prevent a reoccurrence of a recursive loop that Lambda has broken, do the following:

- Reduce your function's available [concurrency](#) to zero, which throttles all future invocations.
- Remove or disable the trigger or event source mapping that's invoking your function.
- Identify and fix code defects that write events back to the AWS resource that's invoking your function. A common source of defects occurs when you use variables to define a function's event source and target. Check that you're not using the same value for both variables.

Additionally, if the event source for your Lambda function is an Amazon SQS queue, then consider [configuring a dead-letter queue](#) on the source queue.

Note

Make sure that you configure the dead-letter queue on the source queue, not on the Lambda function. The dead-letter queue that you configure on a function is used for the function's [asynchronous invocation queue](#), not for event source queues.

If the event source is an Amazon SNS topic, then consider adding an [on-failure destination](#) for your function.

To reduce your function's available concurrency to zero (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function.
3. Choose **Throttle**.
4. In the **Throttle your function** dialog box, choose **Confirm**.

To remove a trigger or event source mapping for your function (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function.

3. Choose the **Configuration** tab, then choose **Triggers**.
4. Under **Triggers**, select the trigger or event source mapping that you want to delete, then choose **Delete**.
5. In the **Delete triggers** dialog box, choose **Delete**.

To disable an event source mapping for your function (AWS CLI)

1. To find the UUID for the event source mapping that you want to disable, run the AWS Command Line Interface (AWS CLI) [list-event-source-mappings](#) command.

```
aws lambda list-event-source-mappings
```

2. To disable the event source mapping, run the following AWS CLI [update-event-source-mapping](#) command.

```
aws lambda update-event-source-mapping --function-name MyFunction \  
--uuid a1b2c3d4-5678-90ab-cdef-EXAMPLE11111 --no-enabled
```

Allowing a Lambda function to run in a recursive loop

If your design intentionally uses a recursive loop, you can configure a Lambda function to allow it to be invoked recursively. We recommend that you avoid using recursive loops in your design. Implementation errors can lead to recursive invocations using all of your AWS account's available concurrency and to unexpected charges being billed to your account.

Important

If you use recursive loops, treat them with caution. Implement best practice guard rails to minimize the risks of implementation errors. To learn more about best practices for using recursive patterns, see [Recursive patterns that cause run-away Lambda functions](#) in Serverless Land.

You can configure functions to allow recursive loops using the Lambda console, the AWS Command Line Interface (AWS CLI), and the [PutFunctionRecursionConfig](#) API. You can also configure a function's recursive loop detection setting in AWS SAM and CloudFormation.

By default, Lambda detects and terminates recursive loops. Unless your design intentionally uses a recursive loop, we recommend that you don't change your functions' default configuration.

Note that when you configure a function to allow recursive loops, the [CloudWatch metric](#) `RecursiveInvocationsDropped` isn't emitted.

Console

To allow a function to run in a recursive loop (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function to open the function detail page.
3. Choose the **Configuration** tab, then choose **Concurrency and recursion detection**.
4. Beside **Recursive loop detection**, choose **Edit**.
5. Select **Allow recursive loops**.
6. Choose **Save**.

AWS CLI

You can use the [PutFunctionRecursionConfig](#) API to allow your function to be invoked in a recursive loop. Specify `Allow` for the recursive loop parameter. For example, you can call this API with the `put-function-recursion-config` AWS CLI command:

```
aws lambda put-function-recursion-config --function-name yourFunctionName --  
recursive-loop Allow
```

You can change your function's configuration back to the default setting so that Lambda terminates recursive loops when it detects them. Edit your function's configuration using the Lambda console or the AWS CLI.

Console

To configure a function so that recursive loops are terminated (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of your function to open the function detail page.
3. Choose the **Configuration** tab, then choose **Concurrency and recursion detection**.

4. Beside **Recursive loop detection**, choose **Edit**.
5. Select **Terminate recursive loops**.
6. Choose **Save**.

AWS CLI

You can use the [PutFunctionRecursionConfig](#) API to configure your function so that Lambda terminates recursive loops when it detects them. Specify **Terminate** for the recursive loop parameter. For example, you can call this API with the `put-function-recursion-config` AWS CLI command:

```
aws lambda put-function-recursion-config --function-name yourFunctionName --  
recursive-loop Terminate
```

Supported Regions for Lambda recursive loop detection

Lambda recursive loop detection is supported in all [commercial Regions](#) except Mexico (Central) and Asia Pacific (New Zealand).

Creating and managing Lambda function URLs

A function URL is a dedicated HTTP(S) endpoint for your Lambda function. You can create and configure a function URL through the Lambda console or the Lambda API.

Tip

Lambda offers two ways to invoke your function through an HTTP endpoint: function URLs and Amazon API Gateway. If you're not sure which is the best method for your use case, see [the section called "Function URLs vs Amazon API Gateway"](#).

When you create a function URL, Lambda automatically generates a unique URL endpoint for you. Once you create a function URL, its URL endpoint never changes. Function URL endpoints have the following format:

```
https://<url-id>.lambda-url.<region>.on.aws
```

Note

Function URLs are not supported in the following AWS Regions: Asia Pacific (Hyderabad) (ap-south-2), Asia Pacific (Melbourne) (ap-southeast-4), Asia Pacific (Malaysia) (ap-southeast-5), Asia Pacific (New Zealand) (ap-southeast-6), Asia Pacific (Thailand) (ap-southeast-7), Asia Pacific (Taipei) (ap-east-2), Canada West (Calgary) (ca-west-1), Europe (Spain) (eu-south-2), Europe (Zurich) (eu-central-2), Israel (Tel Aviv) (il-central-1), and Middle East (UAE) (me-central-1).

Function URLs are dual stack-enabled, supporting IPv4 and IPv6. After you configure a function URL for your function, you can invoke your function through its HTTP(S) endpoint via a web browser, curl, Postman, or any HTTP client.

Note

You can access your function URL through the public Internet only. While Lambda functions do support AWS PrivateLink, function URLs do not.

Lambda function URLs use [resource-based policies](#) for security and access control. Function URLs also support cross-origin resource sharing (CORS) configuration options.

You can apply function URLs to any function alias, or to the \$LATEST unpublished function version. You can't add a function URL to any other function version.

The following section show how to create and manage a function URL using the Lambda console, AWS CLI, and CloudFormation template

Creating a function URL (console)

Follow these steps to create a function URL using the console.

To create a function URL for an existing function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to create the function URL for.
3. Choose the **Configuration** tab, and then choose **Function URL**.
4. Choose **Create function URL**.

5. For **Auth type**, choose **AWS_IAM** or **NONE**. For more information about function URL authentication, see [Access control](#).
6. (Optional) Select **Configure cross-origin resource sharing (CORS)**, and then configure the CORS settings for your function URL. For more information about CORS, see [Cross-origin resource sharing \(CORS\)](#).
7. Choose **Save**.

This creates a function URL for the \$LATEST unpublished version of your function. The function URL appears in the **Function overview** section of the console.

To create a function URL for an existing alias

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function with the alias that you want to create the function URL for.
3. Choose the **Aliases** tab, and then choose the name of the alias that you want to create the function URL for.
4. Choose the **Configuration** tab, and then choose **Function URL**.
5. Choose **Create function URL**.
6. For **Auth type**, choose **AWS_IAM** or **NONE**. For more information about function URL authentication, see [Access control](#).
7. (Optional) Select **Configure cross-origin resource sharing (CORS)**, and then configure the CORS settings for your function URL. For more information about CORS, see [Cross-origin resource sharing \(CORS\)](#).
8. Choose **Save**.

This creates a function URL for your function alias. The function URL appears in the console's **Function overview** section for your alias.

To create a new function with a function URL

To create a new function with a function URL (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose **Create function**.
3. Under **Basic information**, do the following:

- a. For **Function name**, enter a name for your function, such as **my-function**.
 - b. For **Runtime**, choose the language runtime that you prefer, such as **Node.js 24**.
 - c. For **Architecture**, choose either **x86_64** or **arm64**.
 - d. Expand **Permissions**, then choose whether to create a new execution role or use an existing one.
4. Expand **Advanced settings**, and then select **Function URL**.
 5. For **Auth type**, choose **AWS_IAM** or **NONE**. For more information about function URL authentication, see [Access control](#).
 6. (Optional) Select **Configure cross-origin resource sharing (CORS)**. By selecting this option during function creation, your function URL allows requests from all origins by default. You can edit the CORS settings for your function URL after creating the function. For more information about CORS, see [Cross-origin resource sharing \(CORS\)](#).
 7. Choose **Create function**.

This creates a new function with a function URL for the \$LATEST unpublished version of the function. The function URL appears in the **Function overview** section of the console.

Creating a function URL (AWS CLI)

To create a function URL for an existing Lambda function using the AWS Command Line Interface (AWS CLI), run the following command:

```
aws lambda create-function-url-config \  
  --function-name my-function \  
  --qualifier prod \ // optional  
  --auth-type AWS_IAM  
  --cors-config {AllowOrigins="https://example.com"} // optional
```

This adds a function URL to the **prod** qualifier for the function **my-function**. For more information about these configuration parameters, see [CreateFunctionUrlConfig](#) in the API reference.

Note

To create a function URL via the AWS CLI, the function must already exist.

Adding a function URL to a CloudFormation template

To add an `AWS::Lambda::Url` resource to your CloudFormation template, use the following syntax:

JSON

```
{
  "Type" : "AWS::Lambda::Url",
  "Properties" : {
    "AuthType" : String,
    "Cors" : Cors,
    "Qualifier" : String,
    "TargetFunctionArn" : String
  }
}
```

YAML

```
Type: AWS::Lambda::Url
Properties:
  AuthType: String
  Cors:
    Cors
  Qualifier: String
  TargetFunctionArn: String
```

Parameters

- (Required) `AuthType` – Defines the type of authentication for your function URL. Possible values are either `AWS_IAM` or `NONE`. To restrict access to authenticated users only, set to `AWS_IAM`. To bypass IAM authentication and allow any user to make requests to your function, set to `NONE`.
- (Optional) `Cors` – Defines the [CORS settings](#) for your function URL. To add `Cors` to your `AWS::Lambda::Url` resource in CloudFormation, use the following syntax.

Example `AWS::Lambda::Url.Cors` (JSON)

```
{
  "AllowCredentials" : Boolean,
  "AllowHeaders" : [ String, ... ],
```

```
"AllowMethods" : [ String, ... ],
"AllowOrigins" : [ String, ... ],
"ExposeHeaders" : [ String, ... ],
"MaxAge" : Integer
}
```

Example AWS::Lambda::Url.Cors (YAML)

```
AllowCredentials: Boolean
AllowHeaders:
  - String
AllowMethods:
  - String
AllowOrigins:
  - String
ExposeHeaders:
  - String
MaxAge: Integer
```

- (Optional) **Qualifier** – The alias name.
- (Required) **TargetFunctionArn** – The name or Amazon Resource Name (ARN) of the Lambda function. Valid name formats include the following:
 - **Function name** – my-function
 - **Function ARN** – arn:aws:lambda:us-west-2:123456789012:function:my-function
 - **Partial ARN** – 123456789012:function:my-function

Cross-origin resource sharing (CORS)

To define how different origins can access your function URL, use [cross-origin resource sharing \(CORS\)](#). We recommend configuring CORS if you intend to call your function URL from a different domain. Lambda supports the following CORS headers for function URLs.

CORS header	CORS configuration property	Example values
Access-Control-Allow-Origin	AllowOrigins	* (allow all origins) https://www.example.com

CORS header	CORS configuration property	Example values
		http://localhost:60905
Access-Control-Allow-Method	AllowMethods	GET, POST, DELETE, *
Access-Control-Allow-Header	AllowHeaders	Date, Keep-Alive , X-Custom-Header
Access-Control-Expose-Headers	ExposeHeaders	Date, Keep-Alive , X-Custom-Header
Access-Control-Allow-Credentials	AllowCredentials	TRUE
Access-Control-Max-Age	MaxAge	5 (default), 300

When you configure CORS for a function URL using the Lambda console or the AWS CLI, Lambda automatically adds the CORS headers to all responses through the function URL. Alternatively, you can manually add CORS headers to your function response. If there are conflicting headers, the expected behavior depends on the type of request:

- For preflight requests such as OPTIONS requests, the configured CORS headers on the function URL take precedence. Lambda returns only these CORS headers in the response.
- For non-preflight requests such as GET or POST requests, Lambda returns both the configured CORS headers on the function URL, as well as the CORS headers returned by the function. This can result in duplicate CORS headers in the response. You may see an error similar to the following: The 'Access-Control-Allow-Origin' header contains multiple values '*', '*', but only one is allowed.

In general, we recommend configuring all CORS settings on the function URL, rather than sending CORS headers manually in the function response.

Throttling function URLs

Throttling limits the rate at which your function processes requests. This is useful in many situations, such as preventing your function from overloading downstream resources, or handling a sudden surge in requests.

You can throttle the rate of requests that your Lambda function processes through a function URL by configuring reserved concurrency. Reserved concurrency limits the number of maximum concurrent invocations for your function. Your function's maximum request rate per second (RPS) is equivalent to 10 times the configured reserved concurrency. For example, if you configure your function with a reserved concurrency of 100, then the maximum RPS is 1,000.

Whenever your function concurrency exceeds the reserved concurrency, your function URL returns an HTTP 429 status code. If your function receives a request that exceeds the 10x RPS maximum based on your configured reserved concurrency, you also receive an HTTP 429 error. For more information about reserved concurrency, see [Configuring reserved concurrency for a function](#).

Deactivating function URLs

In an emergency, you might want to reject all traffic to your function URL. To deactivate your function URL, set the reserved concurrency to zero. This throttles all requests to your function URL, resulting in HTTP 429 status responses. To reactivate your function URL, delete the reserved concurrency configuration, or set the configuration to an amount greater than zero.

Deleting function URLs

When you delete a function URL, you can't recover it. Creating a new function URL will result in a different URL address.

Note

If you delete a function URL with auth type NONE, Lambda doesn't automatically delete the associated resource-based policy. If you want to delete this policy, you must manually do so.

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function.
3. Choose the **Configuration** tab, and then choose **Function URL**.

4. Choose **Delete**.
5. Enter the word *delete* into the field to confirm the deletion.
6. Choose **Delete**.

 **Note**

When you delete a function that has a function URL, Lambda asynchronously deletes the function URL. If you immediately create a new function with the same name in the same account, it is possible that the original function URL will be mapped to the new function instead of deleted.

Control access to Lambda function URLs

 **Note**

Starting in October 2025, new function URLs will require both `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions.

You can control access to your Lambda function URLs using the [AuthType](#) parameter combined with [resource-based policies](#) attached to your specific function. The configuration of these two components determines who can invoke or perform other administrative actions on your function URL.

The `AuthType` parameter determines how Lambda authenticates or authorizes requests to your function URL. When you configure your function URL, you must specify one of the following `AuthType` options:

- `AWS_IAM` – Lambda uses AWS Identity and Access Management (IAM) to authenticate and authorize requests based on the IAM principal's identity policy and the function's resource-based policy. Choose this option if you want only authenticated users and roles to invoke your function using the function URL.
- `NONE` – Lambda doesn't perform any authentication before invoking your function. However, your function's resource-based policy is always in effect and must grant public access before your

function URL can receive requests. Choose this option to allow public, unauthenticated access to your function URL.

For additional insights into security, you can use AWS Identity and Access Management Access Analyzer to get a comprehensive analysis of external access to your function URL. IAM Access Analyzer also monitors for new or updated permissions on your Lambda functions to help you identify permissions that grant public and cross-account access. You can use IAM Access Analyzer at no charge. To get started with IAM Access Analyzer, see [Using AWS IAM Access Analyzer](#).

This page contains examples of resource-based policies for both auth types, and how to create these policies using the [AddPermission](#) API operation or the Lambda console. For information about how to invoke your function URL after you've set up permissions, see [Invoking Lambda function URLs](#).

Topics

- [Using the AWS_IAM auth type](#)
- [Using the NONE auth type](#)
- [Governance and access control](#)

Using the AWS_IAM auth type

If you choose the AWS_IAM auth type, users who need to invoke your Lambda function URL must have the `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions. Depending on who makes the invocation request, you might have to grant this permission using a [resource-based policy](#).

If the principal making the request is in the same AWS account as the function URL, then the principal must **either** have `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions in their [identity-based policy](#), **or** have permissions granted to them in the function's resource-based policy. In other words, a resource-based policy is optional if the user already has `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions in their identity-based policy. Policy evaluation follows the rules outlined in [Policy evaluation logic](#).

If the principal making the request is in a different account, then the principal must have **both** an identity-based policy that gives them `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions **and** permissions granted to them in a resource-based

policy on the function that they are trying to invoke. Policy evaluation follows the rules outlined in [Determining whether a cross-account request is allowed](#).

The following resource-based policy allows the example role in AWS account 444455556666 to invoke the function URL associated with function my-function. The `lambda:InvokedViaFunctionUrl` context key restricts the `lambda:InvokeFunction` action to function URL calls. This means that the principal must use the function URL to invoke the function. If you don't include `lambda:InvokedViaFunctionUrl`, the principal can invoke your function through other invocation methods, in addition to the function URL.

Example — Cross-account resource-based policy

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "AWS": "arn:aws:iam::444455556666:role/example"
      },
      "Action": "lambda:InvokeFunctionUrl",
      "Resource": "arn:aws:lambda:us-east-1:123456789012:function:my-function",
      "Condition": {
        "StringEquals": {
          "lambda:FunctionUrlAuthType": "AWS_IAM"
        }
      }
    },
    {
      "Effect": "Allow",
      "Principal": {
        "AWS": "arn:aws:iam::444455556666:role/example"
      },
      "Action": "lambda:InvokeFunction",
      "Resource": "arn:aws:lambda:us-east-1:123456789012:function:my-function",
      "Condition": {
        "Bool": {
          "lambda:InvokedViaFunctionUrl": "true"
        }
      }
    }
  ]
}
```

```
}  
]  
}
```

You can create this resource-based policy through the console using the following steps:

To grant URL invocation permissions to another account (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of the function that you want to grant URL invocation permissions for.
3. Choose the **Configuration** tab, and then choose **Permissions**.
4. Under **Resource-based policy**, choose **Add permissions**.
5. Choose **Function URL**.
6. For **Auth type**, choose **AWS_IAM**.
7. Enter a **Statement ID** for your policy statement.
8. For **Principal**, enter the account ID or the Amazon Resource Name (ARN) of the user or role that you want to grant permissions to. For example: **444455556666**.
9. Choose **Save**.

Alternatively, you can create this policy using the following [add-permission](#) AWS Command Line Interface (AWS CLI) commands. When you use the AWS CLI, you must add the `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` statements separately. For example:

```
aws lambda add-permission --function-name my-function \  
  --statement-id UrlPolicyInvokeURL \  
  --action lambda:InvokeFunctionUrl \  
  --principal 444455556666 \  
  --function-url-auth-type AWS_IAM
```

```
aws lambda add-permission --function-name my-function \  
  --statement-id UrlPolicyInvokeFunction \  
  --action lambda:InvokeFunction \  
  --principal 444455556666 \  
  --invoked-via-function-url
```

Using the NONE auth type

Important

When your function URL auth type is NONE and you have a [resource-based policy](#) that grants public access, any unauthenticated user with your function URL can invoke your function.

In some cases, you might want your function URL to be public. For example, you might want to serve requests made directly from a web browser. To allow public access to your function URL, choose the NONE auth type.

If you choose the NONE auth type, Lambda doesn't use IAM to authenticate requests to your function URL. However, your function must have a resource-based policy that allows `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction`. When you create a function URL with auth type NONE using the console or AWS Serverless Application Model (AWS SAM), Lambda automatically creates the resource-based policy for you. If you're using the AWS CLI, AWS CloudFormation, or the Lambda API directly, you must [add the policy yourself](#).

We recommend that you include the [lambda:InvokedViaFunctionUrl](#) context key in your resource-based policies when using the NONE auth type. This context key ensures that the function can only be invoked through the function URL and not through other invocation methods.

Note the following about this policy:

- All entities can call `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction`. This means that anyone who has your function URL can invoke your function.
- The `lambda:FunctionUrlAuthType` condition key value is NONE. This means that the policy statement allows access only when your function URL's auth type is also NONE.
- The `lambda:InvokedViaFunctionUrl` condition ensures that the function can only be invoked through the function URL and not through other invocation methods.

Example — Default resource-based policy for NONE auth type

JSON

```
{
```

```

"Version": "2012-10-17",
"Statement": [
  {
    "Sid": "FunctionURLAllowPublicAccess",
    "Effect": "Allow",
    "Principal": "*",
    "Action": "lambda:InvokeFunctionUrl",
    "Resource": "arn:aws:lambda:us-east-2:123456789012:function:my-function",
    "Condition": {
      "StringEquals": {
        "lambda:FunctionUrlAuthType": "NONE"
      }
    }
  },
  {
    "Sid": "FunctionURLInvokeAllowPublicAccess",
    "Effect": "Allow",
    "Principal": "*",
    "Action": "lambda:InvokeFunction",
    "Resource": "arn:aws:lambda:us-east-2:123456789012:function:my-function",
    "Condition": {
      "Bool": {
        "lambda:InvokedViaFunctionUrl": "true"
      }
    }
  }
]
}

```

Create the resource-based policy using the AWS CLI

Unless you use the console or AWS SAM to create a function URL with auth type NONE, you must add the resource-based policy yourself. Use the following commands to create statements for the `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions. Each statement must be added in a separate command.

```

aws lambda add-permission \
  --function-name UrlTestFunction \
  --statement-id UrlPolicyInvokeURL \
  --action lambda:InvokeFunctionUrl \
  --principal * \

```

```
--function-url-auth-type NONE
```

```
aws lambda add-permission \  
  --function-name UrlTestFunction \  
  --statement-id UrlPolicyInvokeFunction \  
  --action lambda:InvokeFunction \  
  --principal * \  
  --invoked-via-function-url
```

Note

If you delete a function URL with auth type NONE, Lambda doesn't automatically delete the associated resource-based policy. If you want to delete this policy, you must manually do so.

If a function's resource-based policy doesn't grant `lambda:invokeFunctionUrl` and `lambda:InvokeFunction` permissions, users will get a 403 Forbidden error code when they try to invoke your function URL. This will occur even if the function URL uses the NONE auth type.

Governance and access control

In addition to function URL invocation permissions, you can also control access on actions used to configure function URLs. Lambda supports the following IAM policy actions for function URLs:

- `lambda:InvokeFunctionUrl` – Invoke a Lambda function using the function URL.
- `lambda:CreateFunctionUrlConfig` – Create a function URL and set its `AuthType`.
- `lambda:UpdateFunctionUrlConfig` – Update a function URL configuration and its `AuthType`.
- `lambda:GetFunctionUrlConfig` – View the details of a function URL.
- `lambda:ListFunctionUrlConfigs` – List function URL configurations.
- `lambda>DeleteFunctionUrlConfig` – Delete a function URL.

To allow or deny function URL access to other AWS entities, include these actions in IAM policies. For example, the following policy grants the `example` role in AWS account 444455556666 permissions to update the function URL for function **my-function** in account 123456789012.

Example cross-account function URL policy

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "AWS": "arn:aws:iam::444455556666:role/example"
      },
      "Action": "lambda:UpdateFunctionUrlConfig",
      "Resource": "arn:aws:lambda:us-east-2:123456789012:function:my-  
function"
    }
  ]
}
```

Condition keys

For fine-grained access control over your function URLs, use condition context keys. Lambda supports the following context keys for function URLs:

- `lambda:FunctionUrlAuthType` – Defines an enum value describing the auth type that your function URL uses. The value can be either `AWS_IAM` or `NONE`.
- `lambda:InvokedViaFunctionUrl` – Restricts the `lambda:InvokeFunction` action to calls made through the function URL. This ensures that the function can only be invoked using the function URL and not through other invocation methods. For examples of resource-based policies that use the `lambda:InvokedViaFunctionUrl` context key, see the examples in [Using the AWS_IAM auth type](#) and [Using the NONE auth type](#).

You can use these context keys in policies associated with your function. For example, you might want to restrict who can make configuration changes to your function URLs. To deny all `UpdateFunctionUrlConfig` requests to any function with URL auth type `NONE`, you can define the following policy:

Example function URL policy with explicit deny

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Deny",
      "Principal": "*",
      "Action": [
        "lambda:UpdateFunctionUrlConfig"
      ],
      "Resource": "arn:aws:lambda:us-east-1:123456789012:function:*",
      "Condition": {
        "StringEquals": {
          "lambda:FunctionUrlAuthType": "NONE"
        }
      }
    }
  ]
}
```

To grant the example role in AWS account 444455556666 permissions to make `CreateFunctionUrlConfig` and `UpdateFunctionUrlConfig` requests on functions with URL auth type `AWS_IAM`, you can define the following policy:

Example function URL policy with explicit allow

JSON

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "AWS": "arn:aws:iam::444455556666:role/example"
      },
      "Action": [
```

```

        "lambda:CreateFunctionUrlConfig",
        "lambda:UpdateFunctionUrlConfig"
    ],
    "Resource": "arn:aws:lambda:us-east-1:123456789012:function:*",
    "Condition": {
        "StringEquals": {
            "lambda:FunctionUrlAuthType": "AWS_IAM"
        }
    }
}
]
}

```

You can also use this condition key in a [service control policy](#) (SCP). Use SCPs to manage permissions across an entire organization in AWS Organizations. For example, to deny users from creating or updating function URLs that use anything other than the AWS_IAM auth type, use the following service control policy:

Example function URL SCP with explicit deny

JSON

```

{
    "Version": "2012-10-17",
    "Statement": [
        {
            "Effect": "Deny",
            "Action": [
                "lambda:CreateFunctionUrlConfig",
                "lambda:UpdateFunctionUrlConfig"
            ],
            "Resource": "arn:aws:lambda:*:123456789012:function:*",
            "Condition": {
                "StringNotEquals": {
                    "lambda:FunctionUrlAuthType": "AWS_IAM"
                }
            }
        }
    ]
}

```

Invoking Lambda function URLs

A function URL is a dedicated HTTP(S) endpoint for your Lambda function. You can create and configure a function URL through the Lambda console or the Lambda API.

Tip

Lambda offers two ways to invoke your function through an HTTP endpoint: function URLs and Amazon API Gateway. If you're not sure which is the best method for your use case, see [the section called “Function URLs vs Amazon API Gateway”](#).

When you create a function URL, Lambda automatically generates a unique URL endpoint for you. Once you create a function URL, its URL endpoint never changes. Function URL endpoints have the following format:

```
https://<url-id>.lambda-url.<region>.on.aws
```

Note

Function URLs are not supported in the following AWS Regions: Asia Pacific (Hyderabad) (ap-south-2), Asia Pacific (Melbourne) (ap-southeast-4), Asia Pacific (Malaysia) (ap-southeast-5), Asia Pacific (New Zealand) (ap-southeast-6), Asia Pacific (Thailand) (ap-southeast-7), Asia Pacific (Taipei) (ap-east-2), Canada West (Calgary) (ca-west-1), Europe (Spain) (eu-south-2), Europe (Zurich) (eu-central-2), Israel (Tel Aviv) (il-central-1), and Middle East (UAE) (me-central-1).

Function URLs are dual stack-enabled, supporting IPv4 and IPv6. After configuring your function URL, you can invoke your function through its HTTP(S) endpoint via a web browser, curl, Postman, or any HTTP client. To invoke a function URL, you must have `lambda:InvokeFunctionUrl` and `lambda:InvokeFunction` permissions. For more information, see [Access control](#).

Topics

- [Function URL invocation basics](#)
- [Request and response payloads](#)

Function URL invocation basics

If your function URL uses the `AWS_IAM` auth type, you must sign each HTTP request using [AWS Signature Version 4 \(SigV4\)](#). Tools such as [Postman](#) offer built-in ways to sign your requests with SigV4.

If you don't use a tool to sign HTTP requests to your function URL, you must manually sign each request using SigV4. When your function URL receives a request, Lambda also calculates the SigV4 signature. Lambda processes the request only if the signatures match. For instructions on how to manually sign your requests with SigV4, see [Signing AWS requests with Signature Version 4](#) in the *Amazon Web Services General Reference Guide*.

If your function URL uses the `NONE` auth type, you don't have to sign your requests using SigV4. You can invoke your function using a web browser, curl, Postman, or any HTTP client.

To test simple GET requests to your function, use a web browser. For example, if your function URL is `https://abcdefg.lambda-url.us-east-1.on.aws`, and it takes in a string parameter message, your request URL could look like this:

```
https://abcdefg.lambda-url.us-east-1.on.aws/?message=HelloWorld
```

To test other HTTP requests, such as a POST request, you can use a tool such as curl. For example, if you want to include some JSON data in a POST request to your function URL, you could use the following curl command:

```
curl -v 'https://abcdefg.lambda-url.us-east-1.on.aws/?message=HelloWorld' \  
-H 'content-type: application/json' \  
-d '{ "example": "test" }'
```

Request and response payloads

When a client calls your function URL, Lambda maps the request to an event object before passing it to your function. Your function's response is then mapped to an HTTP response that Lambda sends back to the client through the function URL.

The request and response event formats follow the same schema as the [Amazon API Gateway payload format version 2.0](#).

Request payload format

A request payload has the following structure:

```

{
  "version": "2.0",
  "routeKey": "$default",
  "rawPath": "/my/path",
  "rawQueryString": "parameter1=value1&parameter1=value2&parameter2=value",
  "cookies": [
    "cookie1",
    "cookie2"
  ],
  "headers": {
    "header1": "value1",
    "header2": "value1,value2"
  },
  "queryStringParameters": {
    "parameter1": "value1,value2",
    "parameter2": "value"
  },
  "requestContext": {
    "accountId": "123456789012",
    "apiId": "<urlid>",
    "authentication": null,
    "authorizer": {
      "iam": {
        "accessKey": "AKIA...",
        "accountId": "111122223333",
        "callerId": "AIDA...",
        "cognitoIdentity": null,
        "principalOrgId": null,
        "userArn": "arn:aws:iam::111122223333:user/example-user",
        "userId": "AIDA..."
      }
    },
    "domainName": "<url-id>.lambda-url.us-west-2.on.aws",
    "domainPrefix": "<url-id>",
    "http": {
      "method": "POST",
      "path": "/my/path",
      "protocol": "HTTP/1.1",
      "sourceIp": "123.123.123.123",
      "userAgent": "agent"
    },
    "requestId": "id",
    "routeKey": "$default",

```

```

    "stage": "$default",
    "time": "12/Mar/2020:19:03:58 +0000",
    "timeEpoch": 1583348638390
  },
  "body": "Hello from client!",
  "pathParameters": null,
  "isBase64Encoded": false,
  "stageVariables": null
}

```

Parameter	Description	Example
version	The payload format version for this event. Lambda function URLs currently support payload format version 2.0 .	2.0
routeKey	Function URLs don't use this parameter. Lambda sets this to <code>\$default</code> as a placeholder.	<code>\$default</code>
rawPath	The request path. For example, if the request URL is <code>https://{url-id}.lambda-url.{region}.on.aws/example/test/demo</code> , then the raw path value is <code>/example/test/demo</code> .	<code>/example/test/demo</code>
rawQueryString	The raw string containing the request's query string parameters. Supported characters include a-z, A-Z, 0-9, ., _ , -, %, &, =, and +.	<code>"?parameter1=value1&parameter2=value2"</code>

Parameter	Description	Example
<code>cookies</code>	An array containing all cookies sent as part of the request.	<code>["Cookie_1=Value_1", "Cookie_2=Value_2"]</code>
<code>headers</code>	The list of request headers, presented as key-value pairs.	<code>{"header1": "value1", "header2": "value2"}</code>
<code>queryStringParameters</code>	The query parameters for the request. For example, if the request URL is <code>https://{url-id}.lambda-url.{region}.on.aws/example?name=Jane</code> , then the <code>queryStringParameters</code> value is a JSON object with a key of <code>name</code> and a value of <code>Jane</code> .	<code>{"name": "Jane"}</code>
<code>requestContext</code>	An object that contains additional information about the request, such as the <code>requestId</code> , the time of the request, and the identity of the caller if authorized via AWS Identity and Access Management (IAM).	
<code>requestContext.accountId</code>	The AWS account ID of the function owner.	<code>"123456789012"</code>
<code>requestContext.apiId</code>	The ID of the function URL.	<code>"33anwqw8fj"</code>
<code>requestContext.authentication</code>	Function URLs don't use this parameter. Lambda sets this to <code>null</code> .	<code>null</code>

Parameter	Description	Example
<code>requestContext.authorizer</code>	An object that contains information about the caller identity, if the function URL uses the <code>AWS_IAM</code> auth type. Otherwise, Lambda sets this to <code>null</code> .	
<code>requestContext.authorizer.iam.accessKey</code>	The access key of the caller identity.	"AKIAIOSFODNN7EXAMPLE"
<code>requestContext.authorizer.iam.accountId</code>	The AWS account ID of the caller identity.	"111122223333"
<code>requestContext.authorizer.iam.callerId</code>	The ID (user ID) of the caller.	"AIDACKCEVSQ6C2EXAMPLE"
<code>requestContext.authorizer.iam.cognitoIdentity</code>	Function URLs don't use this parameter. Lambda sets this to <code>null</code> or excludes this from the JSON.	<code>null</code>
<code>requestContext.authorizer.iam.principalOrgId</code>	The principal org ID associated with the caller identity.	"AIDACKCEVSQORGEXAMPLE"
<code>requestContext.authorizer.iam.userArn</code>	The user Amazon Resource Name (ARN) of the caller identity.	"arn:aws:iam::111122223333:user/example-user"
<code>requestContext.authorizer.iam.userId</code>	The user ID of the caller identity.	"AIDACOSFODNN7EXAMPLE2"

Parameter	Description	Example
<code>requestContext.domainName</code>	The domain name of the function URL.	"<url-id>.lambda-url.us-west-2.on.aws"
<code>requestContext.domainPrefix</code>	The domain prefix of the function URL.	"<url-id>"
<code>requestContext.http</code>	An object that contains details about the HTTP request.	
<code>requestContext.http.method</code>	The HTTP method used in this request. Valid values include GET, POST, PUT, HEAD, OPTIONS, PATCH, and DELETE.	GET
<code>requestContext.http.path</code>	The request path. For example, if the request URL is <code>https://{url-id}.lambda-url.{region}.on.aws/example/test/demo</code> , then the path value is <code>/example/test/demo</code> .	/example/test/demo
<code>requestContext.http.protocol</code>	The protocol of the request.	HTTP/1.1
<code>requestContext.http.sourceIp</code>	The source IP address of the immediate TCP connection making the request.	123.123.123.123

Parameter	Description	Example
<code>requestContext.http.userAgent</code>	The User-Agent request header value.	Mozilla/5.0 (Macintosh; Intel Mac OS X 10_15_7) Gecko/20100101 Firefox/42.0
<code>requestContext.requestId</code>	The ID of the invocation request. You can use this ID to trace invocation logs related to your function.	e1506fd5-9e7b-434f-bd42-4f8fa224b599
<code>requestContext.routeKey</code>	Function URLs don't use this parameter. Lambda sets this to <code>\$default</code> as a placeholder.	<code>\$default</code>
<code>requestContext.stage</code>	Function URLs don't use this parameter. Lambda sets this to <code>\$default</code> as a placeholder.	<code>\$default</code>
<code>requestContext.time</code>	The timestamp of the request.	"07/Sep/2021:22:50:22 +0000"
<code>requestContext.timeEpoch</code>	The timestamp of the request, in Unix epoch time.	"1631055022677"
<code>body</code>	The body of the request. If the content type of the request is binary, the body is base64-encoded.	{"key1": "value1", "key2": "value2"}
<code>pathParameters</code>	Function URLs don't use this parameter. Lambda sets this to <code>null</code> or excludes this from the JSON.	<code>null</code>

Parameter	Description	Example
isBase64Encoded	TRUE if the body is a binary payload and base64-encoded. FALSE otherwise.	FALSE
stageVariables	Function URLs don't use this parameter. Lambda sets this to null or excludes this from the JSON.	null

Response payload format

When your function returns a response, Lambda parses the response and converts it into an HTTP response. Function response payloads have the following format:

```
{
  "statusCode": 201,
  "headers": {
    "Content-Type": "application/json",
    "My-Custom-Header": "Custom Value"
  },
  "body": "{ \"message\": \"Hello, world!\" }",
  "cookies": [
    "Cookie_1=Value1; Expires=21 Oct 2021 07:48 GMT",
    "Cookie_2=Value2; Max-Age=78000"
  ],
  "isBase64Encoded": false
}
```

Lambda infers the response format for you. If your function returns valid JSON and doesn't return a `statusCode`, Lambda assumes the following:

- `statusCode` is 200.

Note

The valid `statusCode` are within the range of 100 to 599.

- `content-type` is `application/json`.

- `body` is the function response.
- `isBase64Encoded` is `false`.

The following examples show how the output of your Lambda function maps to the response payload, and how the response payload maps to the final HTTP response. When the client invokes your function URL, they see the HTTP response.

Example output for a string response

Lambda function output	Interpreted response output	HTTP response (what the client sees)
<code>"Hello, world!"</code>	<pre>{ "statusCode": 200, "body": "Hello, world!", "headers": { "content-type": "application/json" }, "isBase64Encoded": false }</pre>	<pre>HTTP/2 200 date: Wed, 08 Sep 2021 18:02:24 GMT content-type: applicati on/json content-length: 15 "Hello, world!"</pre>

Example output for a JSON response

Lambda function output	Interpreted response output	HTTP response (what the client sees)
<pre>{ "message": "Hello, world!" }</pre>	<pre>{ "statusCode": 200, "body": { "message": "Hello, world!" }, "headers": { "content-type": "application/json" } }</pre>	<pre>HTTP/2 200 date: Wed, 08 Sep 2021 18:02:24 GMT content-type: applicati on/json content-length: 34 {</pre>

Lambda function output	Interpreted response output	HTTP response (what the client sees)
	<pre> }, "isBase64Encoded": false } </pre>	<pre> "message": "Hello, world!" } </pre>

Example output for a custom response

Lambda function output	Interpreted response output	HTTP response (what the client sees)
<pre> { "statusCode": 201, "headers": { "Content-Type": "application/json", "My-Custom-Header": "Custom Value" }, "body": JSON.stri ngify({ "message": "Hello, world!" }), "isBase64Encoded": false } </pre>	<pre> { "statusCode": 201, "headers": { "Content-Type": "application/json", "My-Custom-Header": "Custom Value" }, "body": JSON.stri ngify({ "message": "Hello, world!" }), "isBase64Encoded": false } </pre>	<pre> HTTP/2 201 date: Wed, 08 Sep 2021 18:02:24 GMT content-type: applicati on/json content-length: 27 my-custom-header: Custom Value { "message": "Hello, world!" } </pre>

Cookies

To return cookies from your function, don't manually add `set-cookie` headers. Instead, include the cookies in your response payload object. Lambda automatically interprets this and adds them as `set-cookie` headers in your HTTP response, as in the following example.

Lambda function output

```
{
  "statusCode": 201,
  "headers": {
    "Content-Type": "application/
json",
    "My-Custom-Header": "Custom
Value"
  },
  "body": JSON.stringify({
    "message": "Hello, world!"
  }),
  "cookies": [
    "Cookie_1=Value1; Expires=21
Oct 2021 07:48 GMT",
    "Cookie_2=Value2; Max-Age=7
8000"
  ],
  "isBase64Encoded": false
}
```

HTTP response (what the client sees)

```
HTTP/2 201
date: Wed, 08 Sep 2021 18:02:24 GMT
content-type: application/json
content-length: 27
my-custom-header: Custom Value
set-cookie: Cookie_1=Value2;
  Expires=21 Oct 2021 07:48 GMT
set-cookie: Cookie_2=Value2; Max-
Age=78000

{
  "message": "Hello, world!"
}
```

Monitoring Lambda function URLs

You can use AWS CloudTrail and Amazon CloudWatch to monitor your function URLs.

Topics

- [Monitoring function URLs with CloudTrail](#)
- [CloudWatch metrics for function URLs](#)

Monitoring function URLs with CloudTrail

For function URLs, Lambda automatically supports logging the following API operations as events in CloudTrail log files:

- [CreateFunctionUrlConfig](#)
- [UpdateFunctionUrlConfig](#)
- [DeleteFunctionUrlConfig](#)
- [GetFunctionUrlConfig](#)
- [ListFunctionUrlConfigs](#)

Each log entry contains information about the caller identity, when the request was made, and other details. You can see all events within the last 90 days by viewing your CloudTrail **Event history**. To retain records past 90 days, you can create a trail.

By default, CloudTrail doesn't log `InvokeFunctionUrl` requests, which are considered data events. However, you can turn on data event logging in CloudTrail. For more information, see [Logging data events for trails](#) in the *AWS CloudTrail User Guide*.

CloudWatch metrics for function URLs

Lambda sends aggregated metrics about function URL requests to CloudWatch. With these metrics, you can monitor your function URLs, build dashboards, and configure alarms in the CloudWatch console.

Function URLs support the following invocation metrics. We recommend viewing these metrics with the Sum statistic.

- `UrlRequestCount` – The number of requests made to this function URL.

- `Url4xxCount` – The number of requests that returned a 4XX HTTP status code. 4XX series codes indicate client-side errors, such as bad requests.
- `Url5xxCount` – The number of requests that returned a 5XX HTTP status code. 5XX series codes indicate server-side errors, such as function errors and timeouts.

Function URLs also support the following performance metric. We recommend viewing this metric with the Average or Max statistics.

- `UrlRequestLatency` – The time between when the function URL receives a request and when the function URL returns a response.

Each of these invocation and performance metrics supports the following dimensions:

- `FunctionName` – View aggregate metrics for function URLs assigned to a function's \$LATEST unpublished version, or to any of the function's aliases. For example, `hello-world-function`.
- `Resource` – View metrics for a specific function URL. This is defined by a function name, along with either the function's \$LATEST unpublished version or one of the function's aliases. For example, `hello-world-function:$LATEST`.
- `ExecutedVersion` – View metrics for a specific function URL based on the executed version. You can use this dimension primarily to track the function URL assigned to the \$LATEST unpublished version.

Select a method to invoke your Lambda function using an HTTP request

Many common use cases for Lambda involve invoking your function using an HTTP request. For example, you might want a web application to invoke your function through a browser request. Lambda functions can also be used to create full REST APIs, handle user interactions from mobile apps, process data from external services via HTTP calls, or create custom webhooks.

The following sections explain what your choices are for invoking Lambda through HTTP and provide information to help you make the right decision for your particular use case.

What are your choices when selecting an HTTP invoke method?

Lambda offers two main methods to invoke a function using an HTTP request - [function URLs](#) and [API Gateway](#). The key differences between these two options are as follows:

- **Lambda function URLs** provide a simple, direct HTTP endpoint for a Lambda function. They are optimized for simplicity and cost-effectiveness and provide the fastest path to expose a Lambda function via HTTP.
- **API Gateway** is a more advanced service for building fully-featured APIs. API Gateway is optimized for building and managing production APIs at scale and provides comprehensive tools for security, monitoring, and traffic management.

Recommendations if you already know your requirements

If you're already clear on your requirements, here are our basic recommendations:

We recommend [function URLs](#) for simple applications or prototyping where you only need basic authentication methods and request/response handling and where you want to keep costs and complexity to a minimum.

[API Gateway](#) is a better choice for production applications at scale or for cases where you need more advanced features like [OpenAPI Description](#) support, a choice of authentication options, custom domain names, or rich request/response handling including throttling, caching, and request/response transformation.

What to consider when selecting a method to invoke your Lambda function

When selecting between function URLs and API Gateway, you need to consider the following factors:

- Your authentication needs, such as whether you require OAuth or Amazon Cognito to authenticate users
- Your scaling requirements and the complexity of the API you want to implement
- Whether you need advanced features such as request validation and request/response formatting
- Your monitoring requirements
- Your cost goals

By understanding these factors, you can select the option that best balances your security, complexity, and cost requirements.

The following information summarizes the main differences between the two options.

Authentication

- **Function URLs** provide basic authentication options through AWS Identity and Access Management (IAM). You can configure your endpoints to be either public (no authentication) or to require IAM authentication. With IAM authentication, you can use standard AWS credentials or IAM roles to control access. While straightforward to set up, this approach provides limited options compared with other authentication methods.
- **API Gateway** provides access to a more comprehensive range of authentication options. As well as IAM authentication, you can use [Lambda authorizers](#) (custom authentication logic), [Amazon Cognito](#) user pools, and OAuth2.0 flows. This flexibility allows you to implement complex authentication schemes, including third-party authentication providers, token-based authentication, and multi-factor authentication.

Request/response handling

- **Function URLs** provide basic HTTP request and response handling. They support standard HTTP methods and include built-in cross-origin resource sharing (CORS) support. While they can handle JSON payloads and query parameters naturally, they don't offer request transformation or validation capabilities. Response handling is similarly straightforward – the client receives the response from your Lambda function exactly as Lambda returns it.
- **API Gateway** provides sophisticated request and response handling capabilities. You can define request validators, transform requests and responses using mapping templates, set up request/response headers, and implement response caching. API Gateway also supports binary payloads and custom domain names and can modify responses before they reach the client. You can set up models for request/response validation and transformation using JSON Schema.

Scaling

- **Function URLs** scale directly with your Lambda function's concurrency limits and handle traffic spikes by scaling your function up to its maximum configured concurrency limit. Once that limit is reached, Lambda responds to additional requests with HTTP 429 responses. There's no built-in queuing mechanism, so handling scaling is entirely dependent on your Lambda function's

configuration. By default, Lambda functions have a limit of 1,000 concurrent executions per AWS Region.

- **API Gateway** provides additional scaling capabilities on top of Lambda's own scaling. It includes built-in request queuing and throttling controls, allowing you to manage traffic spikes more gracefully. API Gateway can handle up to 10,000 requests per second per region by default, with a burst capacity of 5,000 requests per second. It also provides tools to throttle requests at different levels (API, stage, or method) to protect your backend.

Monitoring

- **Function URLs** offer basic monitoring through Amazon CloudWatch metrics, including request count, latency, and error rates. You get access to standard Lambda metrics and logs, which show the raw requests coming into your function. While this provides essential operational visibility, the metrics are focused mainly on function execution.
- **API Gateway** provides comprehensive monitoring capabilities including detailed metrics, logging, and tracing options. You can monitor API calls, latency, error rates, and cache hit/miss rates through CloudWatch. API Gateway also integrates with AWS X-Ray for distributed tracing and provides customizable logging formats.

Cost

- **Function URLs** follow the standard Lambda pricing model – you only pay for function invocations and compute time. There are no additional charges for the URL endpoint itself. This makes it a cost-effective choice for simple APIs or low-traffic applications if you don't need the additional features of API Gateway.
- **API Gateway** offers a [free tier](#) that includes one million API calls received for REST APIs and one million API calls received for HTTP APIs. After this, API Gateway charges for API calls, data transfer, and caching (if enabled). Refer to the API Gateway [pricing page](#) to understand the costs for your own use case.

Other features

- **Function URLs** are designed for simplicity and direct Lambda integration. They support both HTTP and HTTPS endpoints, offer built-in CORS support, and provide dual-stack (IPv4 and IPv6) endpoints. While they lack advanced features, they excel in scenarios where you need a quick, straightforward way to expose Lambda functions via HTTP.

- **API Gateway** includes numerous additional features such as API versioning, stage management, API keys for usage plans, API documentation through Swagger/OpenAPI, WebSocket APIs, private APIs within a VPC, and WAF integration for additional security. It also supports canary deployments, mock integrations for testing, and integration with other AWS services beyond Lambda.

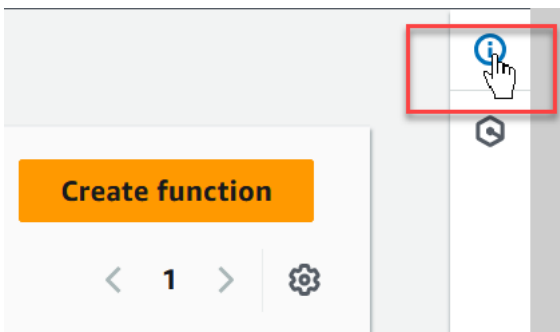

Select a method to invoke your Lambda function

Now that you've read about the criteria for selecting between Lambda function URLs and API Gateway and the key differences between them, you can select the option that best meets your needs and use the following resources to help you get started using it.

Function URLs

Get started with function URLs with the following resources

- Follow the tutorial [Creating a Lambda function with a function URL](#)
- Learn more about function URLs in the [the section called "Function URLs"](#) chapter of this guide
- Try the in-console guided tutorial **Create a simple web app** by doing the following:
 1. Open the [functions page](#) of the Lambda console.
 2. Open the help panel by choosing the icon in the top right corner of the screen.

3. Select **Tutorials**.
4. In **Create a simple web app**, choose **Start tutorial**.

API Gateway

Get started with Lambda and API Gateway with the following resources

- Follow the tutorial [Using Lambda with API Gateway](#) to create a REST API integrated with a backend Lambda function.
- Learn more about the different kinds of API offered by API Gateway in the following sections of the *Amazon API Gateway Developer Guide*:
 - [API Gateway REST APIs](#)
 - [API Gateway HTTP APIs](#)
 - [API Gateway WebSocket APIs](#)
- Try one or more of the examples in the [Tutorials and workshops](#) section of the *Amazon API Gateway Developer Guide*.

Tutorial: Creating a webhook endpoint using a Lambda function URL

In this tutorial, you create a Lambda function URL to implement a webhook endpoint. A webhook is a lightweight, event-driven communication that automatically sends data between applications using HTTP. You can use a webhook to receive immediate updates about events happening in another system, such as when a new customer signs up on a website, a payment is processed, or a file is uploaded.

With Lambda, webhooks can be implemented using either Lambda function URLs or API Gateway. Function URLs are a good choice for simple webhooks that don't require features like advanced authorization or request validation.

Tip

If you're not sure which solution is best for your particular use case, see [the section called "Function URLs vs Amazon API Gateway"](#).

Prerequisites

To complete this tutorial, you must have either Python (version 3.8 or later) or Node.js (version 18 or later) installed on your local machine.

To test the endpoint using an HTTP request, the tutorial uses [curl](#), a command line tool you can use to transfer data using various network protocols. Refer to the [curl documentation](#) to learn how to install the tool if you don't already have it.

Create the Lambda function

First create the Lambda function that runs when an HTTP request is sent to your webhook endpoint. In this example, the sending application sends an update whenever a payment is submitted and indicates in the body of the HTTP request whether the payment was successful. The Lambda function parses the request and takes action according to the status of the payment. In this example, the code just prints the order ID for the payment, but in a real application, you might add the order to a database or send a notification.

The function also implements the most common authentication method used for webhooks, hash-based message authentication (HMAC). With this method, both the sending and receiving applications share a secret key. The sending application uses a hashing algorithm to generate a unique signature using this key together with the message content, and includes the signature

in the webhook request as an HTTP header. The receiving application then repeats this step, generating the signature using the secret key, and compares the resulting value with the signature sent in the request header. If the result matches, the request is considered legitimate.

Create the function using the Lambda console with either the Python or Node.js runtime.

Python

Create the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Create a basic 'Hello world' function by doing the following:
 - a. Choose **Create function**.
 - b. Select **Author from scratch**.
 - c. For **Function name**, enter **myLambdaWebhook**.
 - d. For **Runtime**, select **python3.14**.
 - e. Choose **Create function**.
3. In the **Code source** pane, replace the existing code by copying and pasting the following:

```
import json
import hmac
import hashlib
import os

def lambda_handler(event, context):

    # Get the webhook secret from environment variables
    webhook_secret = os.environ['WEBHOOK_SECRET']

    # Verify the webhook signature
    if not verify_signature(event, webhook_secret):
        return {
            'statusCode': 401,
            'body': json.dumps({'error': 'Invalid signature'})
        }

    try:
        # Parse the webhook payload
        payload = json.loads(event['body'])
```

```
# Handle different event types
event_type = payload.get('type')

if event_type == 'payment.success':
    # Handle successful payment
    order_id = payload.get('orderId')
    print(f"Processing successful payment for order {order_id}")

    # Add your business logic here
    # For example, update database, send notifications, etc.

elif event_type == 'payment.failed':
    # Handle failed payment
    order_id = payload.get('orderId')
    print(f"Processing failed payment for order {order_id}")

    # Add your business logic here

else:
    print(f"Received unhandled event type: {event_type}")

# Return success response
return {
    'statusCode': 200,
    'body': json.dumps({'received': True})
}

except json.JSONDecodeError:
    return {
        'statusCode': 400,
        'body': json.dumps({'error': 'Invalid JSON payload'})
    }

except Exception as e:
    print(f"Error processing webhook: {e}")
    return {
        'statusCode': 500,
        'body': json.dumps({'error': 'Internal server error'})
    }

def verify_signature(event, webhook_secret):
    """
    Verify the webhook signature using HMAC
    """
    try:
```

```
# Get the signature from headers
signature = event['headers'].get('x-webhook-signature')

if not signature:
    print("Error: Missing webhook signature in headers")
    return False

# Get the raw body (return an empty string if the body key doesn't
exist)
body = event.get('body', '')

# Create HMAC using the secret key
expected_signature = hmac.new(
    webhook_secret.encode('utf-8'),
    body.encode('utf-8'),
    hashlib.sha256
).hexdigest()

# Compare the expected signature with the received signature to
authenticate the message
is_valid = hmac.compare_digest(signature, expected_signature)
if not is_valid:
    print(f"Error: Invalid signature. Received: {signature}, Expected:
{expected_signature}")
    return False

return True
except Exception as e:
    print(f"Error verifying signature: {e}")
    return False
```

4. In the **DEPLOY** section, choose **Deploy** to update your function's code.

Node.js

Create the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Create a basic 'Hello world' function by doing the following:
 - a. Choose **Create function**.
 - b. Select **Author from scratch**.

- c. For **Function name**, enter **myLambdaWebhook**.
 - d. For **Runtime**, select **nodejs24.x**.
 - e. Choose **Create function**.
3. In the **Code source** pane, replace the existing code by copying and pasting the following:

```
import crypto from 'crypto';

export const handler = async (event, context) => {
  // Get the webhook secret from environment variables
  const webhookSecret = process.env.WEBHOOK_SECRET;

  // Verify the webhook signature
  if (!verifySignature(event, webhookSecret)) {
    return {
      statusCode: 401,
      body: JSON.stringify({ error: 'Invalid signature' })
    };
  }

  try {
    // Parse the webhook payload
    const payload = JSON.parse(event.body);

    // Handle different event types
    const eventType = payload.type;

    switch (eventType) {
      case 'payment.success': {
        // Handle successful payment
        const orderId = payload.orderId;
        console.log(`Processing successful payment for order ${orderId}`);

        // Add your business logic here
        // For example, update database, send notifications, etc.
        break;
      }

      case 'payment.failed': {
        // Handle failed payment
        const orderId = payload.orderId;
        console.log(`Processing failed payment for order ${orderId}`);
      }
    }
  }
}
```

```
        // Add your business logic here
        break;
    }

    default:
        console.log(`Received unhandled event type: ${eventType}`);
    }

    // Return success response
    return {
        statusCode: 200,
        body: JSON.stringify({ received: true })
    };

} catch (error) {
    if (error instanceof SyntaxError) {
        // Handle JSON parsing errors
        return {
            statusCode: 400,
            body: JSON.stringify({ error: 'Invalid JSON payload' })
        };
    }

    // Handle all other errors
    console.error('Error processing webhook:', error);
    return {
        statusCode: 500,
        body: JSON.stringify({ error: 'Internal server error' })
    };
}

};

// Verify the webhook signature using HMAC

const verifySignature = (event, webhookSecret) => {
    try {
        // Get the signature from headers
        const signature = event.headers['x-webhook-signature'];

        if (!signature) {
            console.log('No signature found in headers:', event.headers);
            return false;
        }
    }
}
```

```
// Get the raw body (return an empty string if the body key doesn't
exist)
const body = event.body || '';

// Create HMAC using the secret key
const hmac = crypto.createHmac('sha256', webhookSecret);
const expectedSignature = hmac.update(body).digest('hex');

// Compare expected and received signatures
const isValid = signature === expectedSignature;
if (!isValid) {
    console.log(`Invalid signature. Received: ${signature}, Expected:
${expectedSignature}`);
    return false;
}

return true;
} catch (error) {
    console.error('Error during signature verification:', error);
    return false;
}
};
```

4. In the **DEPLOY** section, choose **Deploy** to update your function's code.

Create the secret key

For the Lambda function to authenticate the webhook request, it uses a secret key which it shares with the calling application. In this example, the key is stored in an environment variable. In a production application, don't include sensitive information like passwords in your function code. Instead, [create an AWS Secrets Manager secret](#) and then [use the AWS Parameters and Secrets Lambda extension](#) to retrieve your credentials in your Lambda function.

Create and store the webhook secret key

1. Generate a long, random string using a cryptographically secure random number generator. You can use the following code snippets in Python or Node.js to generate and print a 32-character secret, or use your own preferred method.

Python

Example code to generate a secret

```
import secrets
webhook_secret = secrets.token_urlsafe(32)
print(webhook_secret)
```

Node.js

Example code to generate a secret (ES module format)

```
import crypto from 'crypto';
let webhookSecret = crypto.randomBytes(32).toString('base64');
console.log(webhookSecret)
```

2. Store your generated string as an environment variable for your function by doing the following:
 - a. In the **Configuration** tab for your function, select **Environment variables**.
 - b. Choose **Edit**.
 - c. Choose **Add environment variable**.
 - d. For **Key**, enter **WEBHOOK_SECRET**, then for **Value**, enter the secret you generated in the previous step.
 - e. Choose **Save**.

You'll need to use this secret again later in the tutorial to test your function, so make a note of it now.

Create the function URL endpoint

Create an endpoint for your webhook using a Lambda function URL. Because you use the auth type of NONE to create an endpoint with public access, anyone with the URL can invoke your function. To learn more about controlling access to function URLs, see [the section called "Access control"](#). If you need more advanced authentication options for your webhook, consider using API Gateway.

Create the function URL endpoint

1. In the **Configuration** tab for your function, select **Function URL**.
2. Choose **Create function URL**.
3. For **Auth type**, select **NONE**.
4. Choose **Save**.

The endpoint for the function URL you just created is displayed in the **Function URL** pane. Copy the endpoint to use later in the tutorial.

Test the function in the console

Before using an HTTP request to invoke your function using the URL endpoint, test it in the console to confirm your code is working as expected.

To verify the function in the console, you first calculate a webhook signature using the secret you generated earlier in the tutorial with the following test JSON payload:

```
{
  "type": "payment.success",
  "orderId": "1234",
  "amount": "99.99"
}
```

Use either of the following Python or Node.js code examples to calculate the webhook signature using your own secret.

Python

Calculate the webhook signature

1. Save the following code as a file named `calculate_signature.py`. Replace the webhook secret in the code with your own value.

```
import secrets
import hmac
import json
import hashlib
```

```
webhook_secret = "ar1bSDCP86n_1H90s0fL_Qb2NAHBIBQ0yGI0X4Zay4M"

body = json.dumps({"type": "payment.success", "orderId": "1234", "amount":
    "99.99"})

signature = hmac.new(
    webhook_secret.encode('utf-8'),
    body.encode('utf-8'),
    hashlib.sha256
).hexdigest()

print(signature)
```

2. Calculate the signature by running the following command from the same directory you saved the code in. Copy the signature the code outputs.

```
python calculate_signature.py
```

Node.js

Calculate the webhook signature

1. Save the following code as a file named `calculate_signature.mjs`. Replace the webhook secret in the code with your own value.

```
import crypto from 'crypto';

const webhookSecret = "ar1bSDCP86n_1H90s0fL_Qb2NAHBIBQ0yGI0X4Zay4M"
const body = '{"type\\": \\\"payment.success\\", \\\"orderId\\": \\\"1234\\", \\\"amount\\": \\\"99.99\\\"}';

let hmac = crypto.createHmac('sha256', webhookSecret);
let signature = hmac.update(body).digest('hex');

console.log(signature);
```

2. Calculate the signature by running the following command from the same directory you saved the code in. Copy the signature the code outputs.

```
node calculate_signature.mjs
```

You can now test your function code using a test HTTP request in the console.

Test the function in the console

1. Select the **Code** tab for your function.
2. In the **TEST EVENTS** section, choose **Create new test event**
3. For **Event Name**, enter **myEvent**.
4. Replace the existing JSON by copying and pasting the following into the **Event JSON** pane. Replace the webhook signature with the value you calculated in the previous step.

```
{
  "headers": {
    "Content-Type": "application/json",
    "x-webhook-signature":
      "2d672e7a0423fab740fbc040e801d1241f2df32d2ffd8989617a599486553e2a"
  },
  "body": "{\"type\": \"payment.success\", \"orderId\": \"1234\", \"amount\": \"99.99\"}"
}
```

5. Choose **Save**.
6. Choose **Invoke**.

You should see output similar to the following:

Python

```
Status: Succeeded
Test Event Name: myEvent

Response:
{
  "statusCode": 200,
  "body": "{\"received\": true}"
}

Function Logs:
START RequestId: 50cc0788-d70e-453a-9a22-ceaa210e8ac6 Version: $LATEST
Processing successful payment for order 1234
END RequestId: 50cc0788-d70e-453a-9a22-ceaa210e8ac6
```

```
REPORT RequestId: 50cc0788-d70e-453a-9a22-ceaa210e8ac6 Duration: 1.55 ms Billed

```

Test the function using an HTTP request

Use the curl command line tool to test your webhook endpoint.

Test the function using HTTP requests

1. In a terminal or shell program, run the following curl command. Replace the URL with the value for your own function URL endpoint and replace the webhook signature with the signature you calculated using your own secret key.

```
curl -X POST https://ryqgmbx5xjzxahif6frvzikpre0bpvpf.lambda-url.us-west-2.on.aws/
\
-H "Content-Type: application/json" \
-H "x-webhook-
signature: d5f52b76ffba65ff60ea73da67bdf1fc5825d4db56b5d3ffa0b64b7cb85ef48b" \
```

```
-d '{"type": "payment.success", "orderId": "1234", "amount": "99.99"}'
```

You should see the following output:

```
{"received": true}
```

2. Inspect the CloudWatch logs for your function to confirm it parsed the payload correctly by doing the following:
 - a. Open the [Logs group](#) page in the Amazon CloudWatch console.
 - b. Select your function's log group (/aws/lambda/myLambdaWebhook).
 - c. Select the most recent log stream.

You should see output similar to the following in your function's logs:

Python

```
Processing successful payment for order 1234
```

Node.js

```
2025-01-10T18:05:42.062Z e54fe6c7-1df9-4f05-a4c4-0f71cacd64f4 INFO  
Processing successful payment for order 1234
```

3. Confirm that your code detects an invalid signature by running the following curl command. Replace the URL with your own function URL endpoint.

```
curl -X POST https://ryqgmbx5xjzxahif6frvzikpre0bpvpf.lambda-url.us-west-2.on.aws/  
\   
-H "Content-Type: application/json" \  
-H "x-webhook-signature: abcdefg" \  
-d '{"type": "payment.success", "orderId": "1234", "amount": "99.99"}'
```

You should see the following output:

```
{"error": "Invalid signature"}
```

Clean up your resources

You can now delete the resources that you created for this tutorial, unless you want to retain them. By deleting AWS resources that you're no longer using, you prevent unnecessary charges to your AWS account.

To delete the Lambda function

1. Open the [Functions page](#) of the Lambda console.
2. Select the function that you created.
3. Choose **Actions, Delete**.
4. Type **confirm** in the text input field and choose **Delete**.

When you created the Lambda function in the console, Lambda also created an [execution role](#) for your function.

To delete the execution role

1. Open the [Roles page](#) of the IAM console.
2. Select the execution role that Lambda created. The role has the name format `myLambdaWebhook-role-<random string>`.
3. Choose **Delete**.
4. Enter the name of the role in the text input field and choose **Delete**.

Understanding Lambda function scaling

Concurrency is the number of in-flight requests that your AWS Lambda function is handling at the same time. For each concurrent request, Lambda provisions a separate instance of your execution environment. As your functions receive more requests, Lambda automatically handles scaling the number of execution environments until you reach your account's concurrency limit. By default, Lambda provides your account with a total concurrency limit of 1,000 concurrent executions across all functions in an AWS Region. To support your specific account needs, you can [request a quota increase](#) and configure function-level concurrency controls so that your critical functions don't experience throttling.

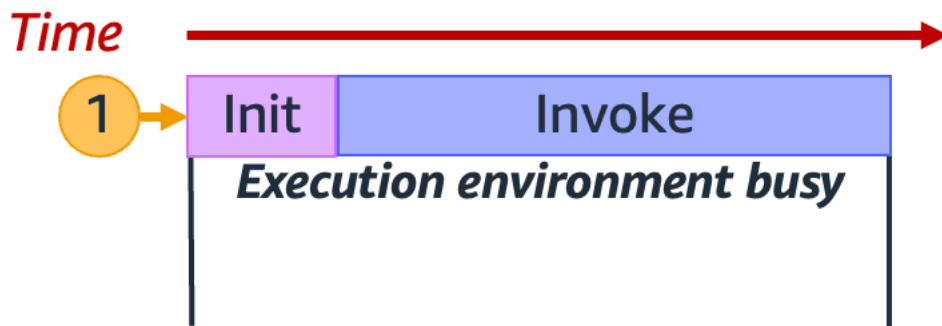

This topic explains concurrency concepts and function scaling in Lambda. By the end of this topic, you'll be able to understand how to calculate concurrency, visualize the two main concurrency control options (reserved and provisioned), estimate appropriate concurrency control settings, and view metrics for further optimization.

- [Monitoring concurrency](#)

Understanding and visualizing concurrency

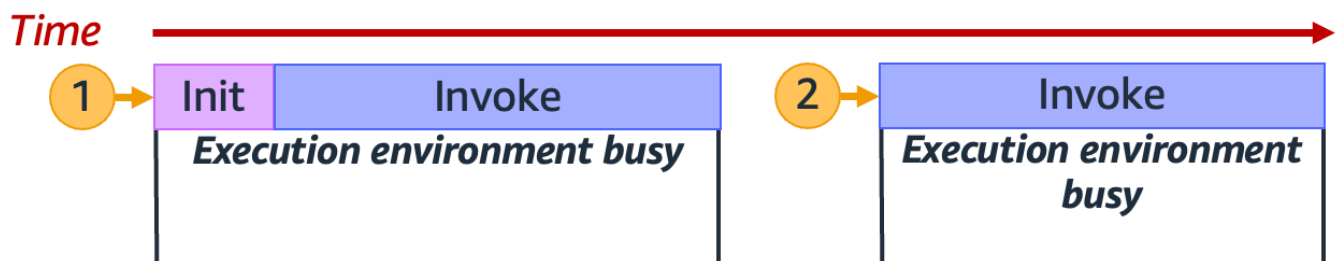

Lambda invokes your function in a secure and isolated [execution environment](#). To handle a request, Lambda must first initialize an execution environment (the [Init phase](#)), before using it to invoke your function (the [Invoke phase](#)):

**Note**

Actual Init and Invoke durations can vary depending on many factors, such as the runtime you choose and the Lambda function code. The previous diagram isn't meant to represent the exact proportions of Init and Invoke phase durations.

The previous diagram uses a rectangle to represent a single execution environment. When your function receives its very first request (represented by the yellow circle with label 1), Lambda creates a new execution environment and runs the code outside your main handler during the Init phase. Then, Lambda runs your function's main handler code during the Invoke phase. During this entire process, this execution environment is busy and cannot process other requests.

When Lambda finishes processing the first request, this execution environment can then process additional requests for the same function. For subsequent requests, Lambda doesn't need to re-initialize the environment.

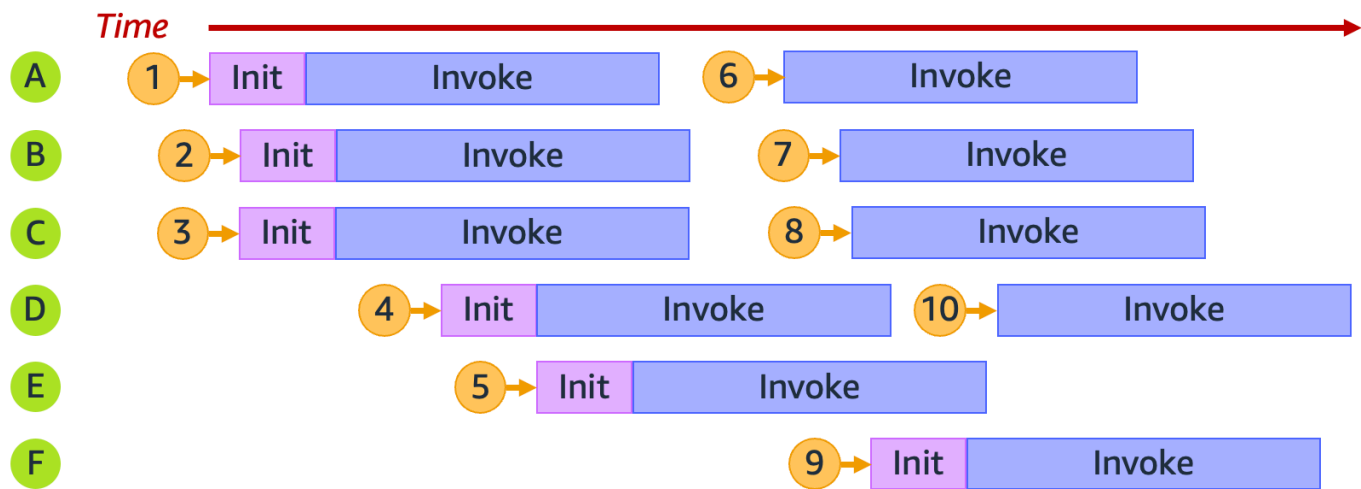

In the previous diagram, Lambda reuses the execution environment to handle the second request (represented by the yellow circle with label 2).

So far, we've focused on just a single instance of your execution environment (that is, a concurrency of 1). In practice, Lambda may need to provision multiple execution environment instances in parallel to handle all incoming requests. When your function receives a new request, one of two things can happen:

- If a pre-initialized execution environment instance is available, Lambda uses it to process the request.
- Otherwise, Lambda creates a new execution environment instance to process the request.

For example, let's explore what happens when your function receives 10 requests:

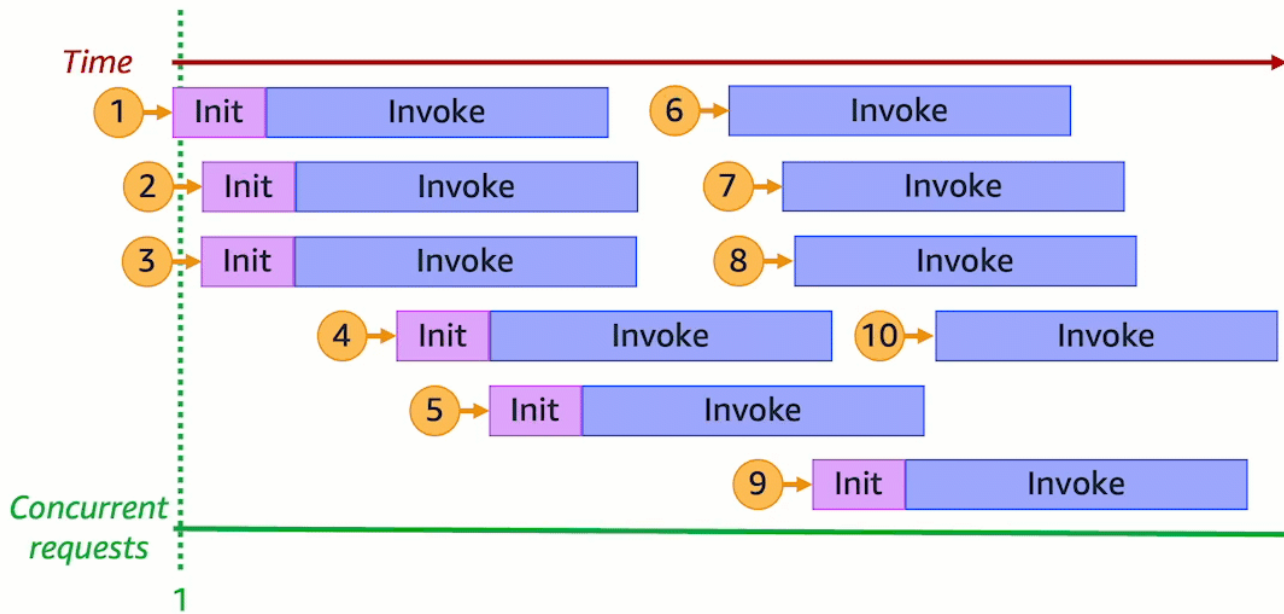

In the previous diagram, each horizontal plane represents a single execution environment instance (labeled from A through F). Here's how Lambda handles each request:

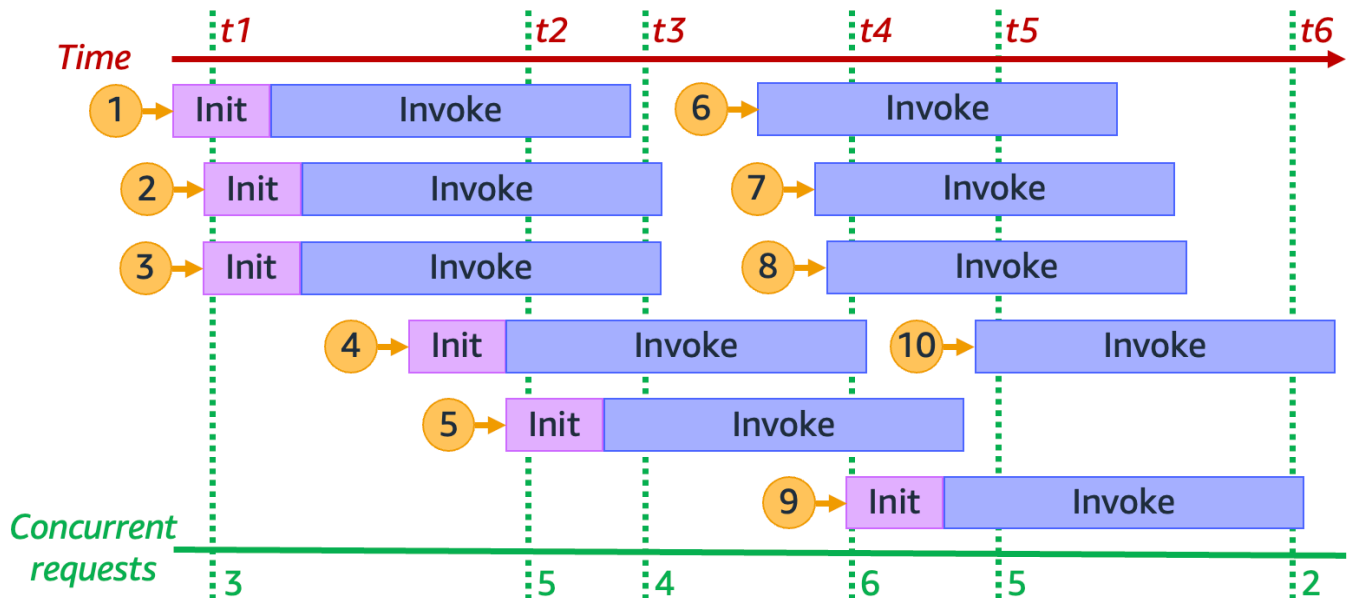

Request	Lambda behavior	Reasoning
1	Provisions new environment A	This is the first request; no execution environment instances are available.
2	Provisions new environment B	Existing execution environment instance A is busy.

Request	Lambda behavior	Reasoning
3	Provisions new environment C	Existing execution environment instances A and B are both busy.
4	Provisions new environment D	Existing execution environment instances A , B , and C are all busy.
5	Provisions new environment E	Existing execution environment instances A , B , C , and D are all busy.
6	Reuses environment A	Execution environment instance A has finished processing request 1 and is now available.
7	Reuses environment B	Execution environment instance B has finished processing request 2 and is now available.
8	Reuses environment C	Execution environment instance C has finished processing request 3 and is now available.
9	Provisions new environment F	Existing execution environment instances A , B , C , D , and E are all busy.
10	Reuses environment D	Execution environment instance D has finished processing request 4 and is now available.

As your function receives more concurrent requests, Lambda scales up the number of execution environment instances in response. The following animation tracks the number of concurrent requests over time:

By freezing the previous animation at six distinct points in time, we get the following diagram:

In the previous diagram, we can draw a vertical line at any point in time and count the number of environments that intersect this line. This gives us the number of concurrent requests at that point in time. For example, at time t_1 , there are three active environments serving three concurrent requests. The maximum number of concurrent requests in this simulation occurs at time t_4 , when there are six active environments serving six concurrent requests.

To summarize, your function's concurrency is the number of concurrent requests that it's handling at the same time. In response to an increase in your function's concurrency, Lambda provisions more execution environment instances to meet request demand.

Calculating concurrency for a function

In general, concurrency of a system is the ability to process more than one task simultaneously. In Lambda, concurrency is the number of in-flight requests that your function is handling at the same time. A quick and practical way of measuring concurrency of a Lambda function is to use the following formula:

$$\text{Concurrency} = (\text{average requests per second}) * (\text{average request duration in seconds})$$

Concurrency differs from requests per second. For example, suppose your function receives 100 requests per second on average. If the average request duration is one second, then it's true that the concurrency is also 100:

$$\text{Concurrency} = (100 \text{ requests/second}) * (1 \text{ second/request}) = 100$$

However, if the average request duration is 500 ms, then the concurrency is 50:

$$\text{Concurrency} = (100 \text{ requests/second}) * (0.5 \text{ second/request}) = 50$$

What does a concurrency of 50 mean in practice? If the average request duration is 500 ms, then you can think of an instance of your function as being able to handle two requests per second. Then, it takes 50 instances of your function to handle a load of 100 requests per second. A concurrency of 50 means that Lambda must provision 50 execution environment instances to efficiently handle this workload without any throttling. Here's how to express this in equation form:

$$\text{Concurrency} = (100 \text{ requests/second}) / (2 \text{ requests/second}) = 50$$

If your function receives double the number of requests (200 requests per second), but only requires half the time to process each request (250 ms), then the concurrency is still 50:

$$\text{Concurrency} = (200 \text{ requests/second}) * (0.25 \text{ second/request}) = 50$$

Test your understanding of concurrency

Suppose you have a function that takes, on average, 200 ms to run. During peak load, you observe 5,000 requests per second. What is the concurrency of your function during peak load?

Answer

The average function duration is 200 ms, or 0.2 seconds. Using the concurrency formula, you can plug in the numbers to get a concurrency of 1,000:

$$\text{Concurrency} = (5,000 \text{ requests/second}) * (0.2 \text{ seconds/request}) = 1,000$$

Alternatively, an average function duration of 200 ms means that your function can process 5 requests per second. To handle the 5,000 request per second workload, you need 1,000 execution environment instances. Thus, the concurrency is 1,000:

$$\text{Concurrency} = (5,000 \text{ requests/second}) / (5 \text{ requests/second}) = 1,000$$

Understanding reserved concurrency and provisioned concurrency

By default, your account has a concurrency limit of 1,000 concurrent executions across all functions in a Region. Your functions share this pool of 1,000 concurrency on an on-demand basis. Your functions experiences throttling (that is, they start to drop requests) if you run out of available concurrency.

Some of your functions might be more critical than others. As a result, you might want to configure concurrency settings to ensure that critical functions get the concurrency that they need. There are two types of concurrency controls available: reserved concurrency and provisioned concurrency.

- Use **reserved concurrency** to set both the maximum and minimum number of concurrent instances to reserve a portion of your account's concurrency for a function. This is useful if you

don't want other functions taking up all the available unreserved concurrency. When a function has reserved concurrency, no other function can use that concurrency.

- Use **provisioned concurrency** to pre-initialize a number of environment instances for a function. This is useful for reducing cold start latencies.

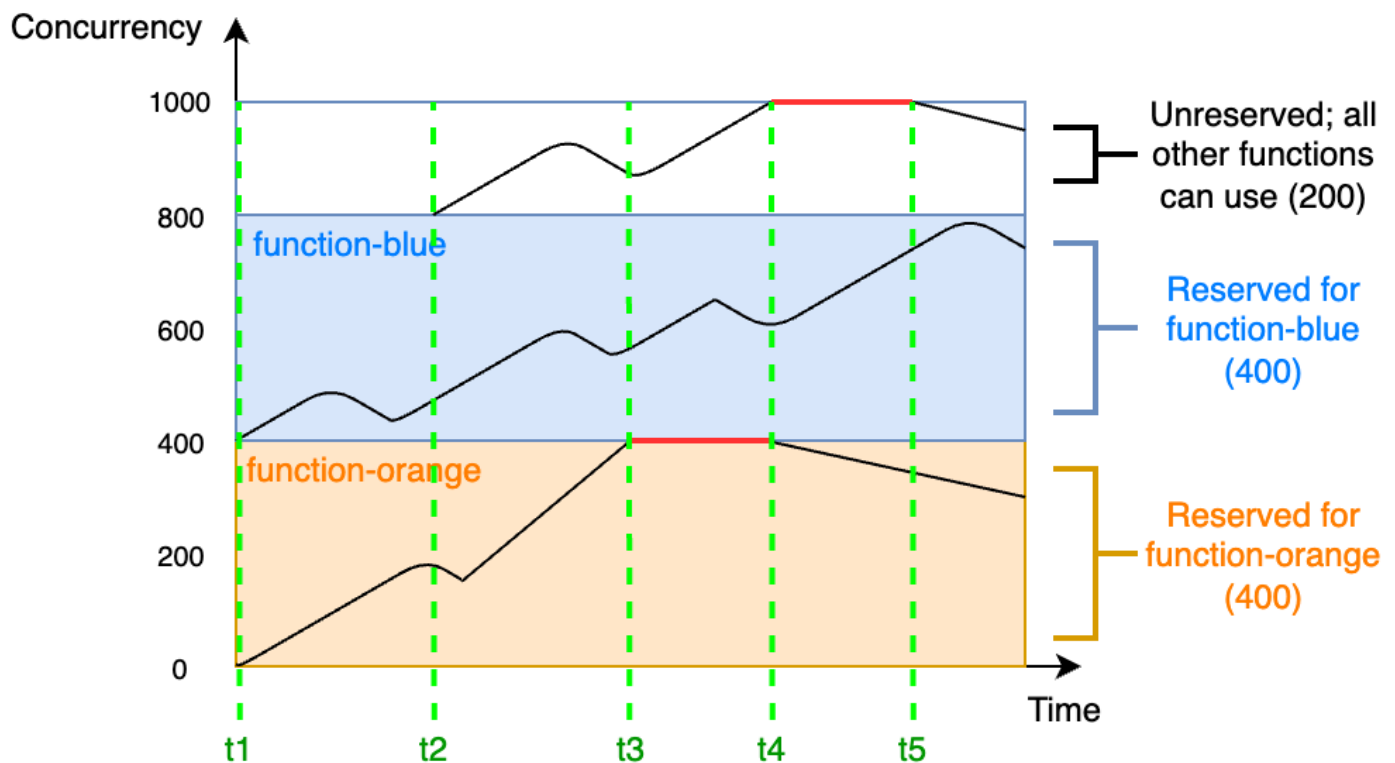

Reserved concurrency

If you want to guarantee that a certain amount of concurrency is available for your function at any time, use reserved concurrency.

Reserved concurrency sets the maximum and minimum number of concurrent instances that you want to allocate to your function. When you dedicate reserved concurrency to a function, no other function can use that concurrency. In other words, setting reserved concurrency can impact the concurrency pool that's available to other functions. Functions that don't have reserved concurrency share the remaining pool of unreserved concurrency.

Configuring reserved concurrency counts towards your overall account concurrency limit. There is no charge for configuring reserved concurrency for a function.

To better understand reserved concurrency, consider the following diagram:

In this diagram, your account concurrency limit for all the functions in this Region is at the default limit of 1,000. Suppose you have two critical functions, function-blue and function-orange, that routinely expect to get high invocation volumes. You decide to give 400 units of reserved concurrency to function-blue, and 400 units of reserved concurrency to function-orange. In this example, all other functions in your account must share the remaining 200 units of unreserved concurrency.

The diagram has five points of interest:

- At t_1 , both function-orange and function-blue begin receiving requests. Each function begins to use up its allocated portion of reserved concurrency units.
- At t_2 , function-orange and function-blue steadily receive more requests. At the same time, you deploy some other Lambda functions, which begin receiving requests. You don't allocate reserved concurrency to these other functions. They begin using the remaining 200 units of unreserved concurrency.
- At t_3 , function-orange hits the max concurrency of 400. Although there is unused concurrency elsewhere in your account, function-orange cannot access it. The red line indicates that function-orange is experiencing throttling, and Lambda may drop requests.
- At t_4 , function-orange starts to receive fewer requests and is no longer throttling. However, your other functions experience a spike in traffic and begin throttling. Although there is unused concurrency elsewhere in your account, these other functions cannot access it. The red line indicates that your other functions are experiencing throttling.
- At t_5 , other functions start to receive fewer requests and are no longer throttling.

From this example, notice that reserving concurrency has the following effects:

- **Your function can scale independently of other functions in your account.** All of your account's functions in the same Region that don't have reserved concurrency share the pool of unreserved concurrency. Without reserved concurrency, other functions can potentially use up all of your available concurrency. This prevents critical functions from scaling up if needed.
- **Your function can't scale out of control.** Reserved concurrency caps your function's maximum and minimum concurrency. This means that your function can't use concurrency reserved for other functions, or concurrency from the unreserved pool. Additionally, reserved concurrency acts as both a lower and upper bound - it reserves the specified capacity exclusively for your function while also preventing it from scaling beyond that limit. You can reserve concurrency

to prevent your function from using all the available concurrency in your account, or from overloading downstream resources.

- **You may not be able to use all of your account's available concurrency.** Reserving concurrency counts towards your account concurrency limit, but this also means that other functions cannot use that chunk of reserved concurrency. If your function doesn't use up all of the concurrency that you reserve for it, you're effectively wasting that concurrency. This isn't an issue unless other functions in your account could benefit from the wasted concurrency.

To learn how to manage reserved concurrency settings for your functions, see [Configuring reserved concurrency for a function](#).

Provisioned concurrency

You use reserved concurrency to define the maximum number of execution environments reserved for a Lambda function. However, none of these environments come pre-initialized. As a result, your function invocations may take longer because Lambda must first initialize the new environment before being able to use it to invoke your function. When Lambda has to initialize a new environment in order to carry out an invocation, this is known as a [cold start](#). To mitigate cold starts, you can use provisioned concurrency.

Provisioned concurrency is the number of pre-initialized execution environments that you want to allocate to your function. If you set provisioned concurrency on a function, Lambda initializes that number of execution environments so that they are prepared to respond immediately to function requests.

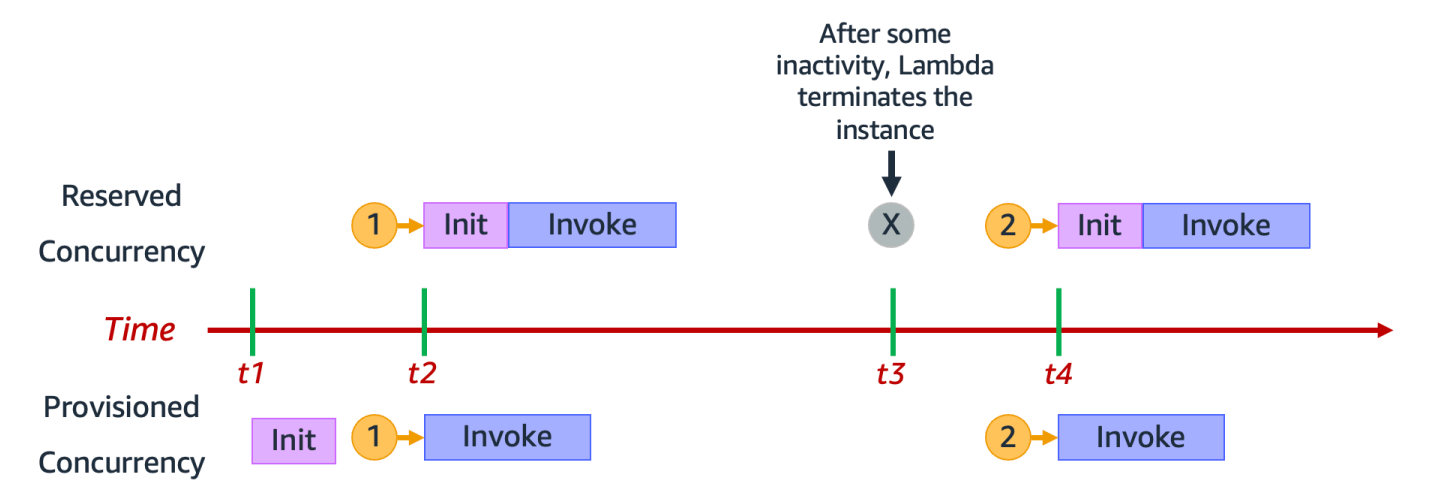

Note

Using provisioned concurrency incurs additional charges to your account. If you're working with the Java 11 or Java 17 runtimes, you can also use Lambda SnapStart to mitigate cold start issues at no additional cost. SnapStart uses cached snapshots of your execution environment to significantly improve startup performance. You cannot use both SnapStart and provisioned concurrency on the same function version. For more information about SnapStart features, limitations, and supported Regions, see [Improving startup performance with Lambda SnapStart](#).

When using provisioned concurrency, Lambda still recycles execution environments in the background. For example, this can occur [after an invocation failure](#). However, at any given time,

Lambda always ensures that the number of pre-initialized environments is equal to the value of your function's provisioned concurrency setting. Importantly, even if you're using provisioned concurrency, you can still experience a cold start delay if Lambda has to reset the execution environment.

In contrast, when using reserved concurrency, Lambda may completely terminate an environment after a period of inactivity. The following diagram illustrates this by comparing the lifecycle of a single execution environment when you configure your function using reserved concurrency compared to provisioned concurrency.

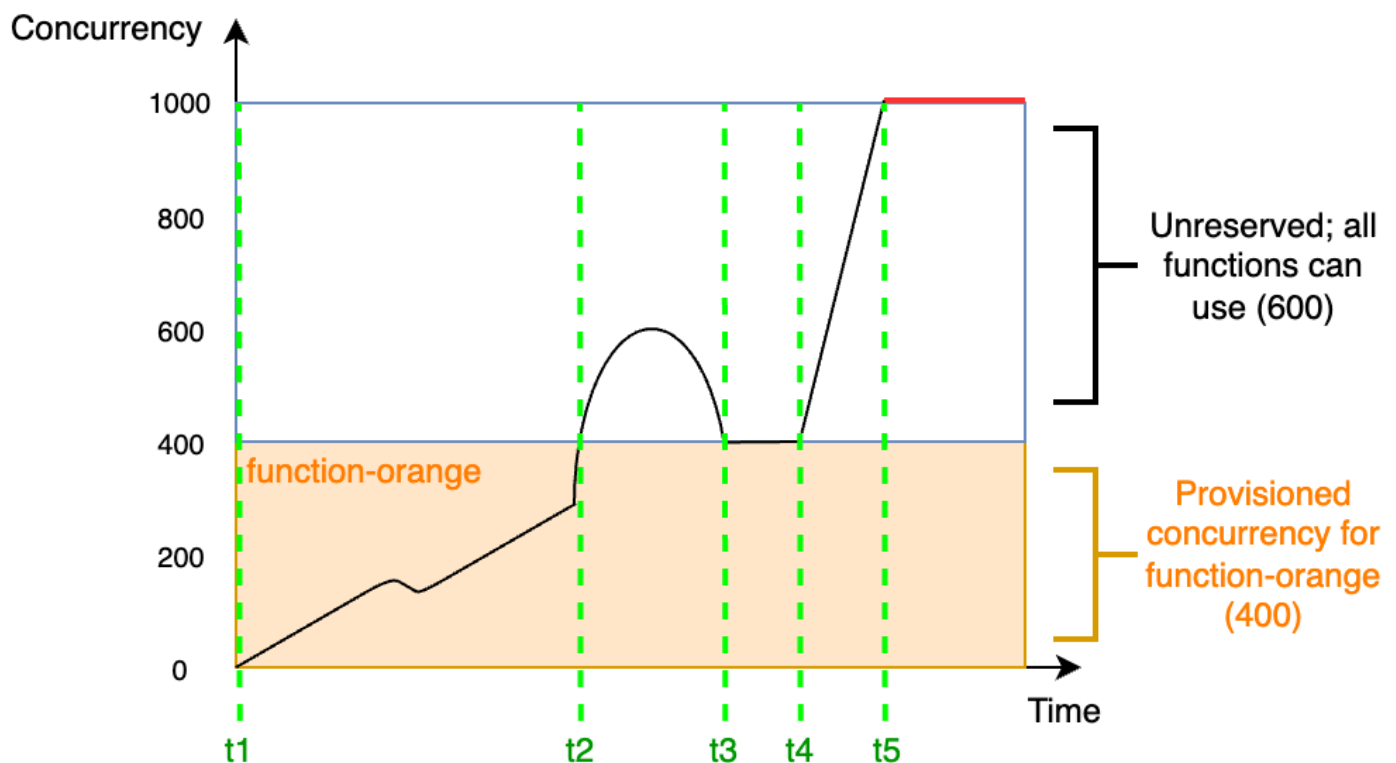

The diagram has four points of interest:

Time	Reserved concurrency	Provisioned concurrency
t1	Nothing happens.	Lambda pre-initializes an execution environment instance.
t2	Request 1 comes in. Lambda must initialize a new execution environment instance.	Request 1 comes in. Lambda uses the pre-initialized environment instance.
t3	After some inactivity, Lambda terminates the active environment instance.	Nothing happens.

Time	Reserved concurrency	Provisioned concurrency
t4	Request 2 comes in. Lambda must initialize a new execution environment instance.	Request 2 comes in. Lambda uses the pre-initialized environment instance.

To better understand provisioned concurrency, consider the following diagram:

In this diagram, you have an account concurrency limit of 1,000. You decide to give 400 units of provisioned concurrency to function-orange. All functions in your account, *including* function-orange, can use the remaining 600 units of unreserved concurrency.

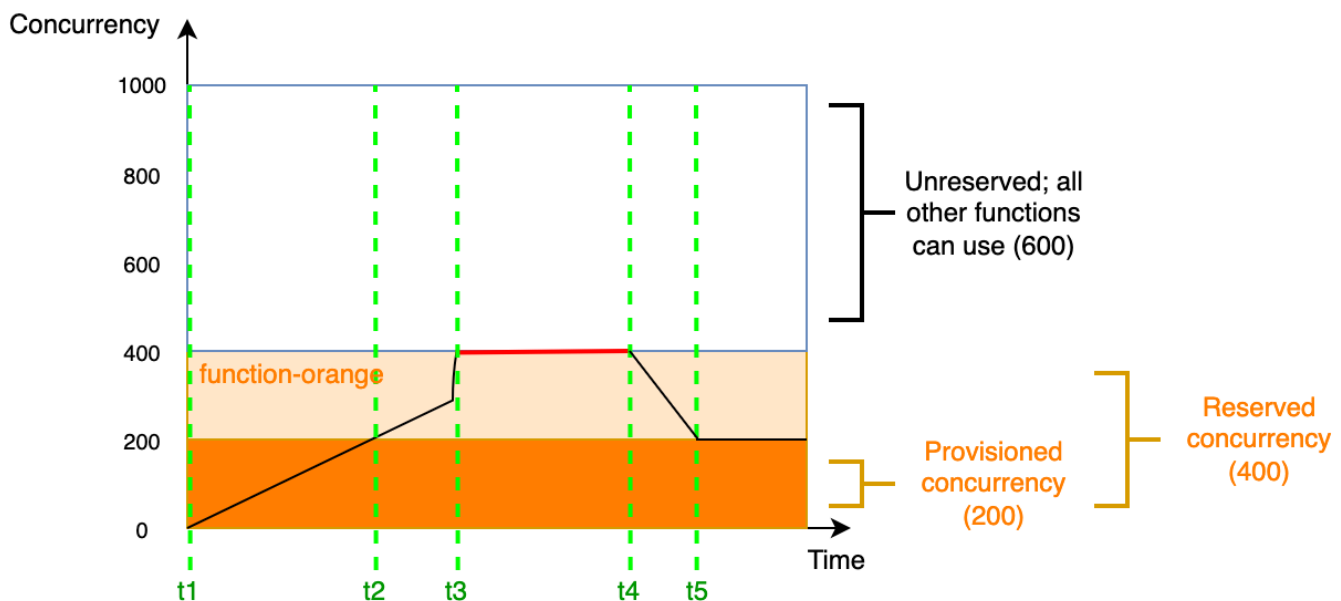

The diagram has five points of interest:

- At t1, function-orange begins receiving requests. Since Lambda has pre-initialized 400 execution environment instances, function-orange is ready for immediate invocation.
- At t2, function-orange reaches 400 concurrent requests. As a result, function-orange runs out of provisioned concurrency. However, since there's still unreserved concurrency available,

Lambda can use this to handle additional requests to function-orange (there's no throttling). Lambda must create new instances to serve these requests, and your function may experience cold start latencies.

- At t3, function-orange returns to 400 concurrent requests after a brief spike in traffic. Lambda is again able to handle all requests without cold start latencies.
- At t4, functions in your account experience a burst in traffic. This burst can come from function-orange or any other function in your account. Lambda uses unreserved concurrency to handle these requests.
- At t5, functions in your account reach the maximum concurrency limit of 1,000, and experience throttling.

The previous example considered only provisioned concurrency. In practice, you can set both provisioned concurrency and reserved concurrency on a function. You might do this if you had a function that handles a consistent load of invocations on weekdays, but routinely sees spikes of traffic on weekends. In this case, you could use provisioned concurrency to set a baseline amount of environments to handle request during weekdays, and use reserved concurrency to handle the weekend spikes. Consider the following diagram:

In this diagram, suppose that you configure 200 units of provisioned concurrency and 400 units of reserved concurrency for function-orange. Because you configured reserved concurrency, function-orange cannot use any of the 600 units of unreserved concurrency.

This diagram has five points of interest:

- At t_1 , function-orange begins receiving requests. Since Lambda has pre-initialized 200 execution environment instances, function-orange is ready for immediate invocation.
- At t_2 , function-orange uses up all its provisioned concurrency. function-orange can continue serving requests using reserved concurrency, but these requests may experience cold start latencies.
- At t_3 , function-orange reaches 400 concurrent requests. As a result, function-orange uses up all its reserved concurrency. Since function-orange cannot use unreserved concurrency, requests begin to throttle.
- At t_4 , function-orange starts to receive fewer requests, and no longer throttles.
- At t_5 , function-orange drops down to 200 concurrent requests, so all requests are again able to use provisioned concurrency (that is, no cold start latencies).

Both reserved concurrency and provisioned concurrency count towards your account concurrency limit and [Regional quotas](#). In other words, allocating reserved and provisioned concurrency can impact the concurrency pool that's available to other functions. Configuring provisioned concurrency incurs charges to your AWS account.

Note

If the amount of provisioned concurrency on a function's versions and aliases adds up to the function's reserved concurrency, then all invocations run on provisioned concurrency. This configuration also has the effect of throttling the unpublished version of the function (\$LATEST), which prevents it from executing. You can't allocate more provisioned concurrency than reserved concurrency for a function.

To manage provisioned concurrency settings for your functions, see [Configuring provisioned concurrency for a function](#). To automate provisioned concurrency scaling based on a schedule or application utilization, see [Using Application Auto Scaling to automate provisioned concurrency management](#).

How Lambda allocates provisioned concurrency

Provisioned concurrency doesn't come online immediately after you configure it. Lambda starts allocating provisioned concurrency after a minute or two of preparation. For each function,

Lambda can provision up to 6,000 execution environments every minute, regardless of AWS Region. This is exactly the same as the [concurrency scaling rate](#) for functions.

When you submit a request to allocate provisioned concurrency, you can't access any of those environments until Lambda completely finishes allocating them. For example, if you request 5,000 provisioned concurrency, none of your requests can use provisioned concurrency until Lambda completely finishes allocating the 5,000 execution environments.

Comparing reserved concurrency and provisioned concurrency

The following table summarizes and compares reserved and provisioned concurrency.

Topic	Reserved concurrency	Provisioned concurrency
Definition	Maximum number of execution environment instances for your function.	Set number of pre-provisioned execution environment instances for your function.
Provisioning behavior	Lambda provisions new instances on an on-demand basis.	Lambda pre-provisions instances (that is, before your function starts receiving requests).
Cold start behavior	Cold start latency possible, since Lambda must create new instances on-demand.	Cold start latency not possible, since Lambda doesn't have to create instances on-demand.
Throttling behavior	Function throttled when reserved concurrency limit reached.	<p>If reserved concurrency not set: function uses unreserved concurrency when provisioned concurrency limit reached.</p> <p>If reserved concurrency set: function throttled when reserved concurrency limit reached.</p>

Topic	Reserved concurrency	Provisioned concurrency
Default behavior if not set	Function uses unreserved concurrency available in your account.	Lambda doesn't pre-provision any instances. Instead, if reserved concurrency not set: function uses unreserved concurrency available in your account. If reserved concurrency set: function uses reserved concurrency.
Pricing	No additional charge.	Incurs additional charges.

Understanding concurrency and requests per second

As mentioned in the previous section, concurrency differs from requests per second. This is an especially important distinction to make when working with functions that have an average request duration of less than 100 ms.

Across all functions in your account, Lambda enforces a requests per second limit that's equal to 10 times your account concurrency. For example, since the default account concurrency limit is 1,000, functions in your account can handle a maximum of 10,000 requests per second.

For example, consider a function with an average request duration of 50 ms. At 20,000 requests per second, here's the concurrency of this function:

$$\text{Concurrency} = (20,000 \text{ requests/second}) * (0.05 \text{ second/request}) = 1,000$$

Based on this result, you might expect that the account concurrency limit of 1,000 is sufficient to handle this load. However, because of the 10,000 requests per second limit, your function can only handle 10,000 requests per second out of the 20,000 total requests. This function experiences throttling.

The lesson is that you must consider both concurrency and requests per second when configuring concurrency settings for your functions. In this case, you need to request an account concurrency limit increase to 2,000, since this would increase your total requests per second limit to 20,000.

Note

Based on this request per second limit, it's incorrect to say that each Lambda execution environment can handle only a maximum of 10 requests per second. Instead of observing the load on any individual execution environment, Lambda only considers overall concurrency and overall requests per second when calculating your quotas.

Test your understanding of concurrency (sub-100 ms functions)

Suppose that you have a function that takes, on average, 20 ms to run. During peak load, you observe 30,000 requests per second. What is the concurrency of your function during peak load?

Answer

The average function duration is 20 ms, or 0.02 seconds. Using the concurrency formula, you can plug in the numbers to get a concurrency of 600:

$$\text{Concurrency} = (30,000 \text{ requests/second}) * (0.02 \text{ seconds/request}) = 600$$

By default, the account concurrency limit of 1,000 seems sufficient to handle this load. However, the requests per second limit of 10,000 isn't enough to handle the incoming 30,000 requests per second. To fully accommodate the 30,000 requests, you need to request an account concurrency limit increase to 3,000 or higher.

The requests per second limit applies to all quotas in Lambda that involve concurrency. In other words, it applies to synchronous on-demand functions, functions that use provisioned concurrency, and [concurrency scaling behavior](#). For example, here are a few scenarios where you must carefully consider both your concurrency and request per second limits:

- A function using on-demand concurrency can experience a burst increase of 500 concurrency every 10 seconds, or by 5,000 requests per second every 10 seconds, whichever happens first.
- Suppose you have a function that has a provisioned concurrency allocation of 10. This function spills over into on-demand concurrency after 10 concurrency or 100 requests per second, whichever happens first.

Concurrency quotas

Lambda sets quotas for the total amount of concurrency that you can use across all functions in a Region. These quotas exist on two levels:

- **At the account level**, your functions can have up to 1,000 units of concurrency by default. To increase this limit, see [Requesting a quota increase](#) in the *Service Quotas User Guide*.
- **At the function level**, you can reserve up to 900 units of concurrency across all your functions by default. Regardless of your total account concurrency limit, Lambda always reserves 100 units of concurrency for your functions that don't explicitly reserve concurrency. For example, if you increased your account concurrency limit to 2,000, then you can reserve up to 1,900 units of concurrency at the function level.
- At both the account level and the function level, Lambda also enforces a requests per second limit of equal to 10 times the corresponding concurrency quota. For instance, this applies to account-level concurrency, functions using on-demand concurrency, functions using provisioned concurrency, and [concurrency scaling behavior](#). For more information, see [the section called "Understanding concurrency and requests per second"](#).

To check your current account level concurrency quota, use the AWS Command Line Interface (AWS CLI) to run the following command:

```
aws lambda get-account-settings
```

You should see output that looks like the following:

```
{
  "AccountLimit": {
    "TotalCodeSize": 80530636800,
    "CodeSizeUnzipped": 262144000,
    "CodeSizeZipped": 52428800,
    "ConcurrentExecutions": 1000,
    "UnreservedConcurrentExecutions": 900
  },
  "AccountUsage": {
    "TotalCodeSize": 410759889,
    "FunctionCount": 8
  }
}
```

`ConcurrentExecutions` is your total account-level concurrency quota.

`UnreservedConcurrentExecutions` is the amount of reserved concurrency that you can still allocate to your functions.

As your function receives more requests, Lambda automatically scales up the number of execution environments to handle these requests until your account reaches its concurrency quota. However, to protect against over-scaling in response to sudden bursts of traffic, Lambda limits how fast your functions can scale. This **concurrency scaling rate** is the maximum rate at which functions in your account can scale in response to increased requests. (That is, how quickly Lambda can create new execution environments.) The concurrency scaling rate differs from the account-level concurrency limit, which is the total amount of concurrency available to your functions.

In each AWS Region, and for each function, your concurrency scaling rate is 1,000 execution environment instances every 10 seconds (or 10,000 requests per second every 10 seconds).

In other words, every 10 seconds, Lambda can allocate at most 1,000 additional execution environment instances, or accommodate 10,000 additional requests per second, to each of your functions.

Usually, you don't need to worry about this limitation. Lambda's scaling rate is sufficient for most use cases.

Importantly, the concurrency scaling rate is a function-level limit. This means that each function in your account can scale independently of other functions.

For more information about scaling behavior, see [Lambda scaling behavior](#).

Configuring reserved concurrency for a function

In Lambda, [concurrency](#) is the number of in-flight requests that your function is currently handling. There are two types of concurrency controls available:

- **Reserved concurrency** – This sets both the maximum and minimum number of concurrent instances allocated to your function. When a function has reserved concurrency, no other function can use that concurrency. Reserved concurrency is useful for ensuring that your most critical functions always have enough concurrency to handle incoming requests. Additionally, reserved concurrency can be used for limiting concurrency to prevent overwhelming downstream resources, like database connections. Reserved concurrency acts as both a lower and upper bound - it reserves the specified capacity exclusively for your function while also preventing it from scaling beyond that limit. Configuring reserved concurrency for a function incurs no additional charges.
- **Provisioned concurrency** – This is the number of pre-initialized execution environments allocated to your function. These execution environments are ready to respond immediately to incoming function requests. Provisioned concurrency is useful for reducing cold start latencies for functions and designed to make functions available with double-digit millisecond response times. Generally, interactive workloads benefit the most from the feature. Those are applications with users initiating requests, such as web and mobile applications, and are the most sensitive to latency. Asynchronous workloads, such as data processing pipelines, are often less latency sensitive and so do not usually need provisioned concurrency. Configuring provisioned concurrency incurs additional charges to your AWS account.

This topic details how to manage and configure reserved concurrency. For a conceptual overview of these two types of concurrency controls, see [Reserved concurrency and provisioned concurrency](#). For information on configuring provisioned concurrency, see [the section called “Configuring provisioned concurrency”](#).

Note

Lambda functions linked to an Amazon MQ event source mapping have a default maximum concurrency. For Apache Active MQ, the maximum number of concurrent instances is 5. For Rabbit MQ, the maximum number of concurrent instances is 1. Setting reserved or provisioned concurrency for your function doesn't change these limits. To request an increase in the default maximum concurrency when using Amazon MQ, contact Support.

Sections

- [Configuring reserved concurrency](#)
- [Accurately estimating required reserved concurrency for a function](#)

Configuring reserved concurrency

You can configure reserved concurrency settings for a function using the Lambda console or the Lambda API.

To reserve concurrency for a function (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function you want to reserve concurrency for.
3. Choose **Configuration** and then choose **Concurrency**.
4. Under **Concurrency**, choose **Edit**.
5. Choose **Reserve concurrency**. Enter the amount of concurrency to reserve for the function.
6. Choose **Save**.

You can reserve up to the **Unreserved account concurrency** value minus 100. The remaining 100 units of concurrency are for functions that aren't using reserved concurrency. For example, if your account has a concurrency limit of 1,000, you cannot reserve all 1,000 units of concurrency to a single function.

Edit concurrency

Concurrency

Unreserved account concurrency: 0

- ☐ Use unreserved account concurrency
- ☒ Reserve concurrency

 The unreserved account concurrency can't go below 100.

Cancel

Save

Reserving concurrency for a function impacts the concurrency pool that's available to other functions. For example, if you reserve 100 units of concurrency for function-a, other functions in your account must share the remaining 900 units of concurrency, even if function-a doesn't use all 100 reserved concurrency units.

To intentionally throttle a function, set its reserved concurrency to 0. This stops your function from processing any events until you remove the limit.

To configure reserved concurrency with the Lambda API, use the following API operations.

- [PutFunctionConcurrency](#)
- [GetFunctionConcurrency](#)
- [DeleteFunctionConcurrency](#)

For example, to configure reserved concurrency with the AWS Command Line Interface (CLI), use the `put-function-concurrency` command. The following command reserves 100 concurrency units for a function named `my-function`:

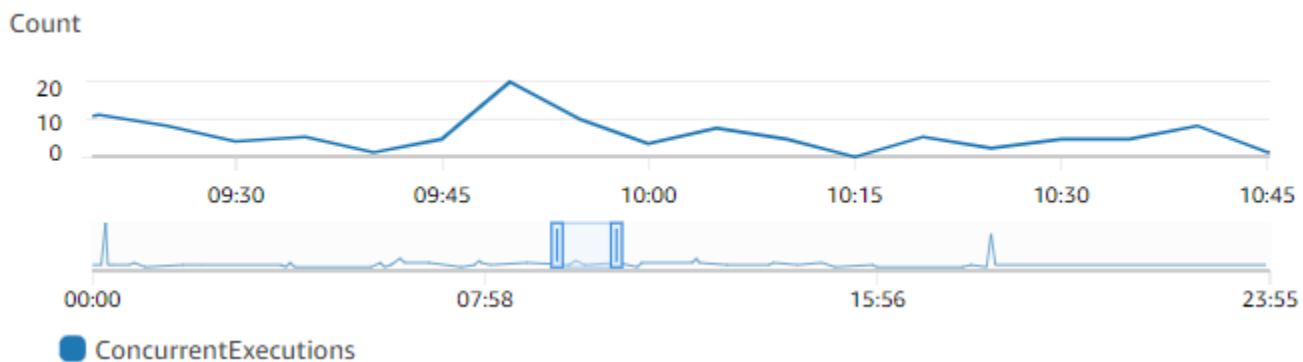

```
aws lambda put-function-concurrency --function-name my-function \  
--reserved-concurrent-executions 100
```

You should see output that looks like the following:

```
{
  "ReservedConcurrentExecutions": 100
}
```

Accurately estimating required reserved concurrency for a function

If your function is currently serving traffic, you can easily view its concurrency metrics using [CloudWatch metrics](#). Specifically, the `ConcurrentExecutions` metric shows you the number of concurrent invocations for each function in your account.

The previous graph suggests that this function serves an average of 5 to 10 concurrent requests at any given time, and peaks at 20 requests on a typical day. Suppose that there are many other functions in your account. **If this function is critical to your application and you don't want to drop any requests**, use a number greater than or equal to 20 as your reserved concurrency setting.

Alternatively, recall that you can also [calculate concurrency](#) using the following formula:

```
Concurrency = (average requests per second) * (average request duration in seconds)
```

Multiplying average requests per second with the average request duration in seconds gives you a rough estimate of how much concurrency you need to reserve. You can estimate average requests per second using the `Invocation` metric, and the average request duration in seconds using the `Duration` metric. See [Using CloudWatch metrics with Lambda](#) for more details.

You should also be familiar with your upstream and downstream throughput constraints. While Lambda functions scale seamlessly with load, upstream and downstream dependencies may not have the same throughput capabilities. If you need to limit how high your function can scale, configure reserved concurrency on your function.

Configuring provisioned concurrency for a function

In Lambda, [concurrency](#) is the number of in-flight requests that your function is currently handling. There are two types of concurrency controls available:

- **Reserved concurrency** – This sets both the maximum and minimum number of concurrent instances allocated to your function. When a function has reserved concurrency, no other function can use that concurrency. Reserved concurrency is useful for ensuring that your most critical functions always have enough concurrency to handle incoming requests. Additionally, reserved concurrency can be used for limiting concurrency to prevent overwhelming downstream resources, like database connections. Reserved concurrency acts as both a lower and upper bound - it reserves the specified capacity exclusively for your function while also preventing it from scaling beyond that limit. Configuring reserved concurrency for a function incurs no additional charges.
- **Provisioned concurrency** – This is the number of pre-initialized execution environments allocated to your function. These execution environments are ready to respond immediately to incoming function requests. Provisioned concurrency is useful for reducing cold start latencies for functions and designed to make functions available with double-digit millisecond response times. Generally, interactive workloads benefit the most from the feature. Those are applications with users initiating requests, such as web and mobile applications, and are the most sensitive to latency. Asynchronous workloads, such as data processing pipelines, are often less latency sensitive and so do not usually need provisioned concurrency. Configuring provisioned concurrency incurs additional charges to your AWS account.

This topic details how to manage and configure provisioned concurrency. For a conceptual overview of these two types of concurrency controls, see [Reserved concurrency and provisioned concurrency](#). For more information on configuring reserved concurrency, see [the section called “Configuring reserved concurrency”](#).

Note

Lambda functions linked to an Amazon MQ event source mapping have a default maximum concurrency. For Apache Active MQ, the maximum number of concurrent instances is 5. For Rabbit MQ, the maximum number of concurrent instances is 1. Setting reserved or provisioned concurrency for your function doesn't change these limits. To request an increase in the default maximum concurrency when using Amazon MQ, contact Support.

- [Optimizing function code when using provisioned concurrency](#)
- [Using environment variables to view and control provisioned concurrency behavior](#)
- [Understanding logging and billing behavior with provisioned concurrency](#)
- [Using Application Auto Scaling to automate provisioned concurrency management](#)

Configuring provisioned concurrency

You can configure provisioned concurrency settings for a function using the Lambda console or the Lambda API.

To allocate provisioned concurrency for a function (console)

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function you want to allocate provisioned concurrency for.
3. Choose **Configuration** and then choose **Concurrency**.
4. Under **Provisioned concurrency configurations**, choose **Add configuration**.
5. Choose the qualifier type, and alias or version.

Note

You cannot use provisioned concurrency with the `$LATEST` version of any function. If your function has an event source, make sure that event source points to the correct function alias or version. Otherwise, your function won't use provisioned concurrency environments.

6. Enter a number under **Provisioned concurrency**.
7. Choose **Save**.

You can configure up to the **Unreserved account concurrency** in your account, minus 100. The remaining 100 units of concurrency are for functions that aren't using reserved concurrency. For example, if your account has a concurrency limit of 1,000, and you haven't assigned any reserved

or provisioned concurrency to any of your other functions, you can configure a maximum of 900 provisioned concurrency units for a single function.

Provisioned concurrency

To enable your function to scale without fluctuations in latency, use provisioned concurrency. You can use Application Auto Scaling to automatically adjust provisioned concurrency to maintain a configured target utilization. Provisioned concurrency runs continually and has separate pricing for concurrency and execution duration. [Learn more](#) 

\$0.00 per month in addition to pricing for duration and requests. [Pricing](#) 

 The maximum allowed provisioned concurrency is 900, based on the unreserved concurrency available (1000) minus the minimum unreserved account concurrency (100).

900 available

 Please correct the errors above.

Configuring provisioned concurrency for a function has an impact on the concurrency pool available to other functions. For instance, if you configure 100 units of provisioned concurrency for function-a, other functions in your account must share the remaining 900 units of concurrency. This is true even if function-a doesn't use all 100 units.

It's possible to allocate both reserved concurrency and provisioned concurrency for the same function. In such cases, the provisioned concurrency cannot exceed the reserved concurrency.

This limitation extends to function versions. The maximum provisioned concurrency you can assign to a specific function version is the function's reserved concurrency minus the provisioned concurrency on other function versions.

To configure provisioned concurrency with the Lambda API, use the following API operations.

- [PutProvisionedConcurrencyConfig](#)
- [GetProvisionedConcurrencyConfig](#)
- [ListProvisionedConcurrencyConfigs](#)
- [DeleteProvisionedConcurrencyConfig](#)

For example, to configure provisioned concurrency with the AWS Command Line Interface (CLI), use the `put-provisioned-concurrency-config` command. The following command allocates 100 units of provisioned concurrency for the BLUE alias of a function named `my-function`:

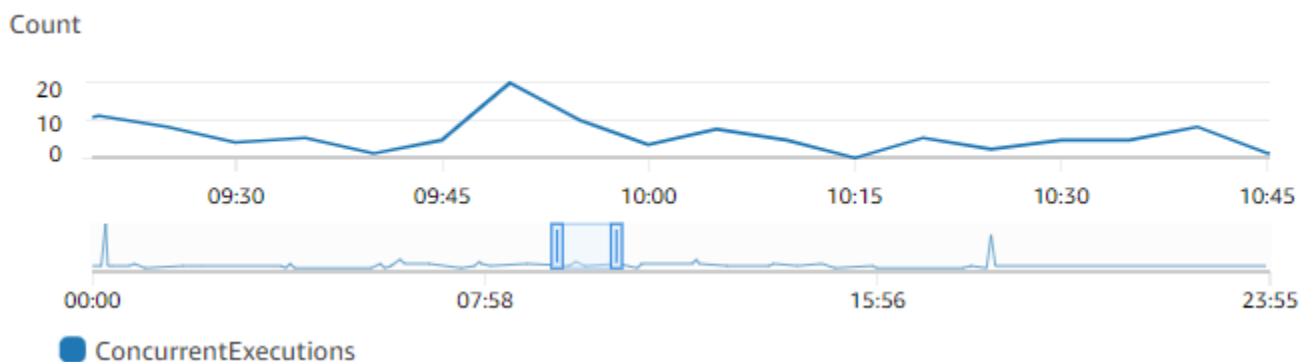

```
aws lambda put-provisioned-concurrency-config --function-name my-function \  
--qualifier BLUE \  
--provisioned-concurrent-executions 100
```

You should see output that looks like the following:

```
{  
  "Requested ProvisionedConcurrentExecutions": 100,  
  "Allocated ProvisionedConcurrentExecutions": 0,  
  "Status": "IN_PROGRESS",  
  "LastModified": "2023-01-21T11:30:00+0000"  
}
```

Accurately estimating required provisioned concurrency for a function

You can view any active function's concurrency metrics using [CloudWatch metrics](#). Specifically, the `ConcurrentExecutions` metric shows you the number of concurrent invocations for functions in your account.

The previous graph suggests that this function serves an average of 5 to 10 concurrent requests at any given time, and peaks at 20 requests. Suppose that there are many other functions in your account. **If this function is critical to your application and you need a low-latency response on every invocation**, configure at least 20 units of provisioned concurrency.

Recall that you can also [calculate concurrency](#) using the following formula:

```
Concurrency = (average requests per second) * (average request duration in seconds)
```

To estimate how much concurrency you need, multiply average requests per second with the average request duration in seconds. You can estimate average requests per second using the `Invocation` metric, and the average request duration in seconds using the `Duration` metric.

When configuring provisioned concurrency, Lambda suggests adding a 10% buffer on top of the amount of concurrency your function typically needs. For example, if your function usually peaks at 200 concurrent requests, set the provisioned concurrency to 220 (200 concurrent requests + 10% = 220 provisioned concurrency).

Optimizing function code when using provisioned concurrency

If you're using provisioned concurrency, consider restructuring your function code to optimize for low latency. For functions using provisioned concurrency, Lambda runs any initialization code, such as loading libraries and instantiating clients, during allocation time. Therefore, it's advisable to move as much initialization outside of the main function handler to avoid impacting latency during actual function invocations. In contrast, initializing libraries or instantiating clients within your main handler code means your function must run this each time it's invoked (this occurs regardless of whether you're using provisioned concurrency).

For on-demand invocations, Lambda may need to rerun your initialization code every time your function experiences a cold start. For such functions, you may choose to defer initialization of a specific capability until your function needs it. For example, consider the following control flow for a Lambda handler:

```
def handler(event, context):
    ...
    if ( some_condition ):
        // Initialize CLIENT_A to perform a task
    else:
        // Do nothing
```

In the previous example, instead of initializing `CLIENT_A` outside of the main handler, the developer initialized it within the `if` statement. By doing this, Lambda runs this code only if `some_condition` is met. If you initialize `CLIENT_A` outside the main handler, Lambda runs that code on every cold start. This can increase overall latency.

You can measure cold starts as Lambda scales up by adding X-Ray monitoring to your function. A function using provisioned concurrency does not exhibit cold start behavior since the execution environment is prepared ahead of invocation. However, provisioned concurrency must be applied

to a [specific version or alias](#) of a function, not the \$LATEST version. In cases where you continue to see cold start behavior, ensure that you are invoking the version of alias with provisioned concurrency configured.

Using environment variables to view and control provisioned concurrency behavior

It's possible for your function to use up all of its provisioned concurrency. Lambda uses on-demand instances to handle any excess traffic. To determine the type of initialization Lambda used for a specific environment, check the value of the `AWS_LAMBDA_INITIALIZATION_TYPE` environment variable. This variable has two possible values: `provisioned-concurrency` or `on-demand`. The value of `AWS_LAMBDA_INITIALIZATION_TYPE` is immutable and remains constant throughout the lifetime of the environment. To check the value of an environment variable in your function code, see [Retrieving Lambda environment variables](#).

If you're using the .NET 8 runtime, you can configure the `AWS_LAMBDA_DOTNET_PREJIT` environment variable to improve the latency for functions, even if they don't use provisioned concurrency. The .NET runtime employs lazy compilation and initialization for each library that your code calls for the first time. As a result, the first invocation of a Lambda function may take longer than subsequent ones. To mitigate this, you can choose one of three values for `AWS_LAMBDA_DOTNET_PREJIT`:

- `ProvisionedConcurrency`: Lambda performs ahead-of-time JIT compilation for all environments using provisioned concurrency. This is the default value.
- `Always`: Lambda performs ahead-of-time JIT compilation for every environment, even if the function doesn't use provisioned concurrency.
- `Never`: Lambda disables ahead-of-time JIT compilation for all environments.

Understanding logging and billing behavior with provisioned concurrency

For provisioned concurrency environments, your function's initialization code runs during allocation, and periodically as Lambda recycles instances of your environment. Lambda bills you for initialization even if the environment instance never processes a request. Provisioned concurrency runs continually and incurs separate billing from initialization and invocation costs. For more details, see [AWS Lambda Pricing](#).

When you configure a Lambda function with provisioned concurrency, Lambda pre-initializes that execution environment so that it's available ahead of invocation requests. Lambda logs the [Init Duration field](#) of the function in a [platform-initReport](#) log event in JSON logging format every time the environment is initialized. To see this log event, configure your [JSON log level](#) to at least INFO. You can also use the [Telemetry API](#) to consume platform events where the Init Duration field is reported.

Using Application Auto Scaling to automate provisioned concurrency management

You can use Application Auto Scaling to manage provisioned concurrency on a schedule or based on utilization. If your function receives predictable traffic patterns, use scheduled scaling. If you want your function to maintain a specific utilization percentage, use a target tracking scaling policy.

Note

If you use Application Auto Scaling to manage your function's provisioned concurrency, ensure that you [configure an initial provisioned concurrency value](#) first. If your function doesn't have an initial provisioned concurrency value, Application Auto Scaling may not handle function scaling properly.

Scheduled scaling

With Application Auto Scaling, you can set your own scaling schedule according to predictable load changes. For more information and examples, see [Scheduled scaling for Application Auto Scaling](#) in the Application Auto Scaling User Guide, and [Scheduling AWS Lambda Provisioned Concurrency for recurring peak usage](#) on the AWS Compute Blog.

Target tracking

With target tracking, Application Auto Scaling creates and manages a set of CloudWatch alarms based on how you define your scaling policy. When these alarms activate, Application Auto Scaling automatically adjusts the amount of environments allocated using provisioned concurrency. Use target tracking for applications that don't have predictable traffic patterns.

To scale provisioned concurrency using target tracking, use the `RegisterScalableTarget` and `PutScalingPolicy` Application Auto Scaling API operations. For example, if you're using the AWS Command Line Interface (CLI), follow these steps:

1. Register a function's alias as a scaling target. The following example registers the BLUE alias of a function named `my-function`:

```
aws application-autoscaling register-scalable-target --service-namespace lambda \
--resource-id function:my-function:BLUE --min-capacity 1 --max-capacity 100 \
--scalable-dimension lambda:function:ProvisionedConcurrency
```

2. Apply a scaling policy to the target. The following example configures Application Auto Scaling to adjust the provisioned concurrency configuration for an alias to keep utilization near 70 percent, but you can apply any value between 10% and 90%.

```
aws application-autoscaling put-scaling-policy \
--service-namespace lambda \
--scalable-dimension lambda:function:ProvisionedConcurrency \
--resource-id function:my-function:BLUE \
--policy-name my-policy \
--policy-type TargetTrackingScaling \
--target-tracking-scaling-policy-configuration '{ "TargetValue":
0.7, "PredefinedMetricSpecification": { "PredefinedMetricType":
"LambdaProvisionedConcurrencyUtilization" } }'
```

You should see output that looks like this:

```
{
  "PolicyARN": "arn:aws:autoscaling:us-
east-2:123456789012:scalingPolicy:12266dbb-1524-xmpl-a64e-9a0a34b996fa:resource/lambda/
function:my-function:BLUE:policyName/my-policy",
  "Alarms": [
    {
      "AlarmName": "TargetTracking-function:my-function:BLUE-AlarmHigh-aed0e274-
xmpl-40fe-8cba-2e78f000c0a7",
      "AlarmARN": "arn:aws:cloudwatch:us-
east-2:123456789012:alarm:TargetTracking-function:my-function:BLUE-AlarmHigh-aed0e274-
xmpl-40fe-8cba-2e78f000c0a7"
    },
    {
```

```
    "AlarmName": "TargetTracking-function:my-function:BLUE-AlarmLow-7e1a928e-  
xmpl-4d2b-8c01-782321bc6f66",  
    "AlarmARN": "arn:aws:cloudwatch:us-  
east-2:123456789012:alarm:TargetTracking-function:my-function:BLUE-AlarmLow-7e1a928e-  
xmpl-4d2b-8c01-782321bc6f66"  
  }  
]  
}
```

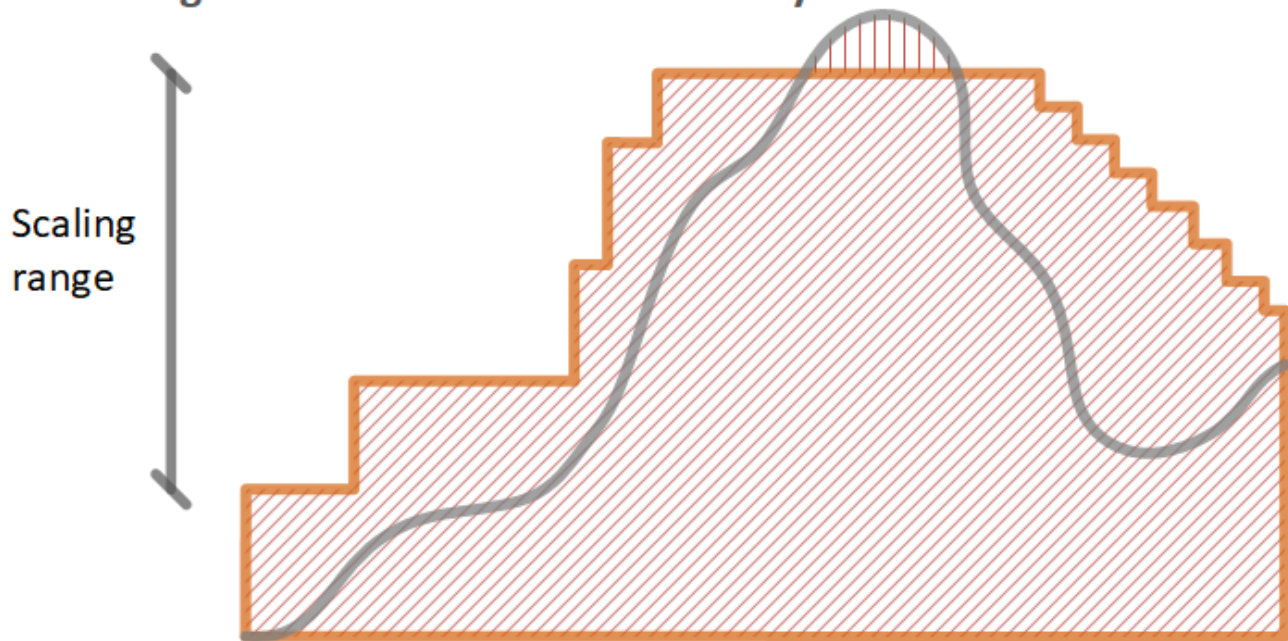

Application Auto Scaling creates two alarms in CloudWatch. The first alarm triggers when the utilization of provisioned concurrency consistently exceeds 70%. When this happens, Application Auto Scaling allocates more provisioned concurrency to reduce utilization. The second alarm triggers when utilization is consistently less than 63% (90 percent of the 70% target). When this happens, Application Auto Scaling reduces the alias's provisioned concurrency.

 **Note**

Lambda emits the `ProvisionedConcurrencyUtilization` metric only when your function is active and receiving requests. During periods of inactivity, no metrics are emitted, and your auto-scaling alarms will enter the `INSUFFICIENT_DATA` state. As a result, Application Auto Scaling won't be able to adjust your function's provisioned concurrency. This may lead to unexpected billing.

In the following example, a function scales between a minimum and maximum amount of provisioned concurrency based on utilization.

Autoscaling with Provisioned Concurrency

Legend

-  Function instances
-  Open requests
-  Provisioned concurrency
-  Standard concurrency

When the number of open requests increase, Application Auto Scaling increases provisioned concurrency in large steps until it reaches the configured maximum. After this, the function can continue to scale on standard, unreserved concurrency if you haven't reached your account concurrency limit. When utilization drops and stays low, Application Auto Scaling decreases provisioned concurrency in smaller periodic steps.

Both of the Application Auto Scaling alarms use the average statistic by default. Functions that experience quick bursts of traffic may not trigger these alarms. For example, suppose your Lambda function executes quickly (i.e. 20-100 ms) and your traffic comes in quick bursts. In this case, the number of requests exceeds the allocated provisioned concurrency during the burst. However, Application Auto Scaling requires the burst load to sustain for at least 3 minutes in order to provision additional environments. Additionally, both CloudWatch alarms require 3 data points that hit the target average to activate the auto scaling policy. If your function experiences quick bursts of traffic, using the **Maximum** statistic instead of the **Average** statistic can be more effective at scaling provisioned concurrency to minimize cold starts.

For more information on target tracking scaling policies, see [Target tracking scaling policies for Application Auto Scaling](#).

Lambda scaling behavior

As your function receives more requests, Lambda automatically scales up the number of execution environments to handle these requests until your account reaches its concurrency quota. However, to protect against over-scaling in response to sudden bursts of traffic, Lambda limits how fast your functions can scale. This **concurrency scaling rate** is the maximum rate at which functions in your account can scale in response to increased requests. (That is, how quickly Lambda can create new execution environments.) The concurrency scaling rate differs from the account-level concurrency limit, which is the total amount of concurrency available to your functions.

Concurrency scaling rate

In each AWS Region, and for each function, your concurrency scaling rate is 1,000 execution environment instances every 10 seconds (or 10,000 requests per second every 10 seconds).

In other words, every 10 seconds, Lambda can allocate at most 1,000 additional execution environment instances, or accommodate 10,000 additional requests per second, to each of your functions.

Usually, you don't need to worry about this limitation. Lambda's scaling rate is sufficient for most use cases.

Importantly, the concurrency scaling rate is a function-level limit. This means that each function in your account can scale independently of other functions.

Note

In practice, Lambda makes a best attempt to refill your concurrency scaling rate continuously over time, rather than in one single refill of 1,000 units every 10 seconds.

Lambda doesn't accrue unused portions of your concurrency scaling rate. This means that at any instant in time, your scaling rate is always 1,000 concurrency units at maximum. For example, if you don't use any of your available 1,000 concurrency units in a 10-second interval, you won't accrue 1,000 additional units in the next 10-second interval. Your concurrency scaling rate is still 1,000 in the next 10-second interval.

As long as your function continues to receive increasing numbers of requests, then Lambda scales at the fastest rate available to you, up to your account's concurrency limit. You can limit the

amount of concurrency that individual functions can use by [configuring reserved concurrency](#). If requests come in faster than your function can scale, or if your function is at maximum concurrency, then additional requests fail with a throttling error (429 status code).

Monitoring concurrency

Lambda emits Amazon CloudWatch metrics to help you monitor concurrency for your functions. This topic explains these metrics and how to interpret them.

Sections

- [General concurrency metrics](#)
- [Provisioned concurrency metrics](#)
- [Working with the ClaimedAccountConcurrency metric](#)

General concurrency metrics

Use the following metrics to monitor concurrency for your Lambda functions. The granularity for each metric is 1 minute.

- **ConcurrentExecutions** – The number of active concurrent invocations at a given point in time. Lambda emits this metric for all functions, versions, and aliases. For any function in the Lambda console, Lambda displays the graph for ConcurrentExecutions natively in the **Monitoring** tab, under **Metrics**. View this metric using **MAX**.
- **UnreservedConcurrentExecutions** – The number of active concurrent invocations that are using unreserved concurrency. Lambda emits this metric across all functions in a region. View this metric using **MAX**.
- **ClaimedAccountConcurrency** – The amount of concurrency that is unavailable for on-demand invocations. ClaimedAccountConcurrency is equal to UnreservedConcurrentExecutions plus the amount of allocated concurrency (i.e. the total reserved concurrency plus total provisioned concurrency). If ClaimedAccountConcurrency exceeds your account concurrency limit, you can [request a higher account concurrency limit](#). View this metric using **MAX**. For more information, see [Working with the ClaimedAccountConcurrency metric](#).

Provisioned concurrency metrics

Use the following metrics to monitor Lambda functions using provisioned concurrency. The granularity for each metric is 1 minute.

- `ProvisionedConcurrentExecutions` – The number of execution environment instances that are actively processing an invocation on provisioned concurrency. Lambda emits this metric for each function version and alias with provisioned concurrency configured. View this metric using **MAX**.

`ProvisionedConcurrentExecutions` is not the same as the total number of provisioned concurrency that you allocate. For example, suppose you allocate 100 units of provisioned concurrency to a function version. During any given minute, if at most 50 out of those 100 execution environments were handling invocations simultaneously, then the value of `MAX(ProvisionedConcurrentExecutions)` is 50.

- `ProvisionedConcurrencyInvocations` – The number of times Lambda invokes your function code using provisioned concurrency. Lambda emits this metric for each function version and alias with provisioned concurrency configured. View this metric using **SUM**.

`ProvisionedConcurrencyInvocations` differs from `ProvisionedConcurrentExecutions` in that `ProvisionedConcurrencyInvocations` counts total number of invocations, while `ProvisionedConcurrentExecutions` counts number of active environments. To understand this distinction, consider the following scenario:

In this example, suppose that you receive 1 invocation per minute, and each invocation takes 2 minutes to complete. Each orange horizontal bar represents a single request. Suppose that you allocate 10 units of provisioned concurrency to this function, such that each request runs on provisioned concurrency.

In between minutes 0 and 1, Request 1 comes in. **At minute 1**, the value for **MAX(ProvisionedConcurrentExecutions)** is 1, since at most 1 execution environment was active during the past minute. The value for **SUM(ProvisionedConcurrencyInvocations)** is also 1, since 1 new request came in during the past minute.

In between minutes 1 and 2, Request 2 comes in, and Request 1 continues to run. **At minute 2**, the value for **MAX(ProvisionedConcurrentExecutions)** is 2, since at most 2 execution environments were active during the past minute. However, the value for **SUM(ProvisionedConcurrencyInvocations)** is 1, since only 1 new request came in during the past minute. This metric behavior continues until the end of the example.

- **ProvisionedConcurrencySpilloverInvocations** – The number of times Lambda invokes your function on standard (reserved or unreserved) concurrency when all provisioned concurrency is in use. Lambda emits this metric for each function version and alias with provisioned concurrency configured. View this metric using **SUM**. The value of **ProvisionedConcurrencyInvocations** + **ProvisionedConcurrencySpilloverInvocations** should be equal to the total number of function invocations (i.e. the **Invocations** metric).

ProvisionedConcurrencyUtilization – The percentage of provisioned concurrency in use (i.e. the value of **ProvisionedConcurrentExecutions** divided by the total amount of provisioned concurrency allocated). Lambda emits this metric for each function version and alias with provisioned concurrency configured. View this metric using **MAX**.

For example, suppose you provision 100 units of provisioned concurrency to a function version. During any given minute, if at most 60 out of those 100 execution environments were handling invocations simultaneously, then the value of **MAX(ProvisionedConcurrentExecutions)** is 60, and the value of **MAX(ProvisionedConcurrencyUtilization)** is 0.6.

A high value for **ProvisionedConcurrencySpilloverInvocations** may indicate that you need to allocate additional provisioned concurrency for your function. Alternatively, you can [configure Application Auto Scaling to handle automatic scaling of provisioned concurrency](#) based on pre-defined thresholds.

Conversely, consistently low values for **ProvisionedConcurrencyUtilization** may indicate that you over-allocated provisioned concurrency for your function.

Working with the ClaimedAccountConcurrency metric

Lambda uses the ClaimedAccountConcurrency metric to determine how much concurrency your account is available for on-demand invocations. Lambda calculates ClaimedAccountConcurrency using the following formula:

$$\text{ClaimedAccountConcurrency} = \text{UnreservedConcurrentExecutions} + (\text{allocated concurrency})$$

UnreservedConcurrentExecutions is the number of active concurrent invocations that are using unreserved concurrency. Allocated concurrency is the sum of the following two parts (substituting RC as "reserved concurrency" and PC as "provisioned concurrency"):

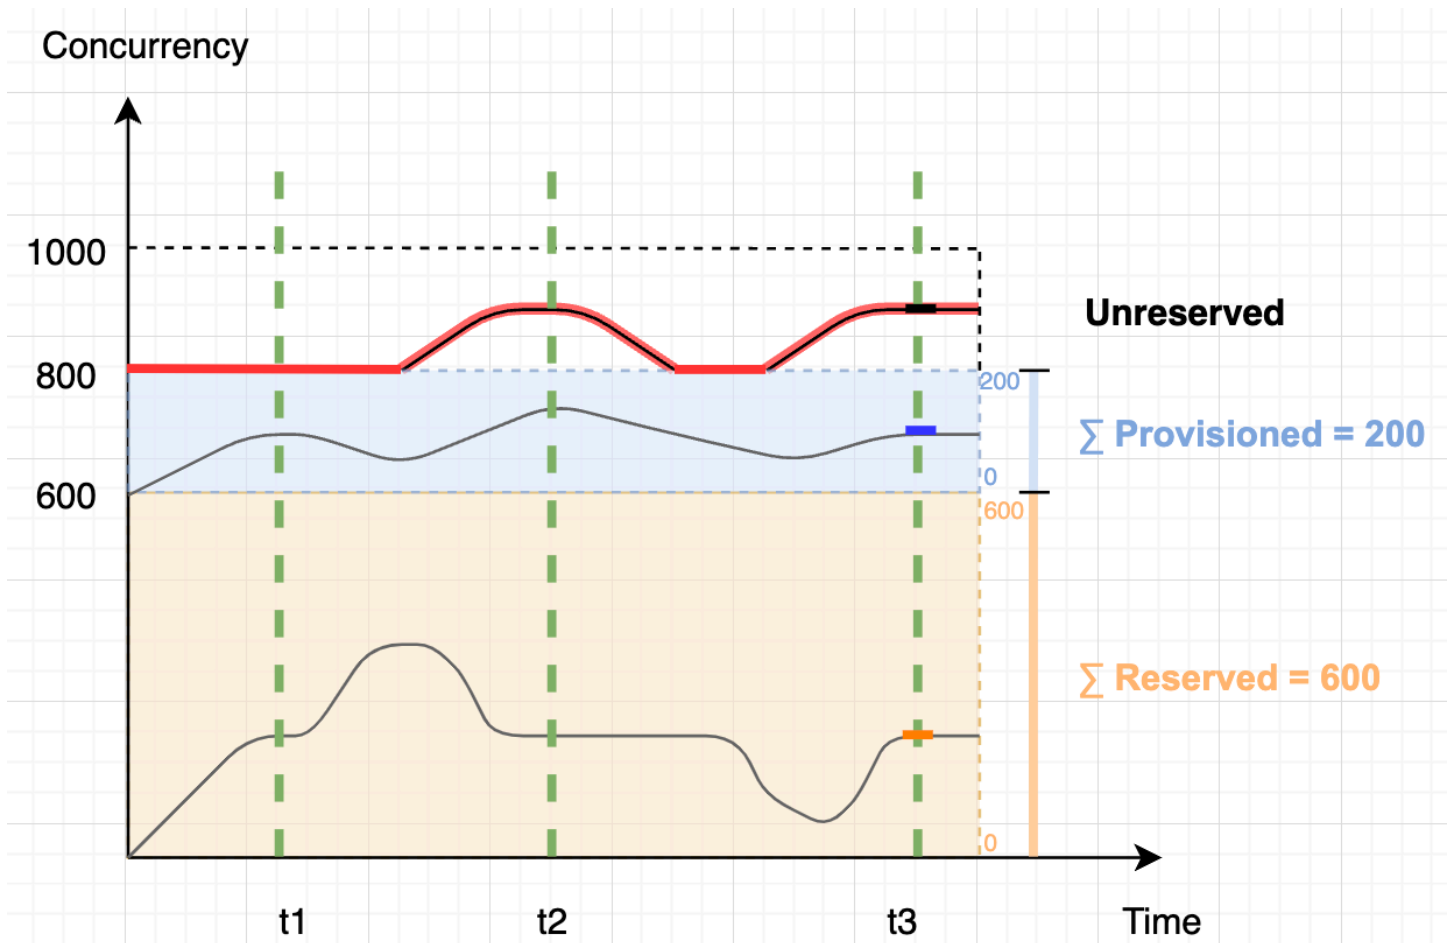

- The total RC across all functions in a Region.
- The total PC across all functions in a Region that use PC, excluding functions that use RC.

Note

You can't allocate more PC than RC for a function. Thus, a function's RC is always greater than or equal to its PC. To calculate the contribution to allocated concurrency for such functions with both PC and RC, Lambda considers only RC, which is the maximum of the two.

Lambda uses the ClaimedAccountConcurrency metric, rather than ConcurrentExecutions, to determine how much concurrency is available for on-demand invocations. While the ConcurrentExecutions metric is useful for tracking the number of active concurrent invocations, it doesn't always reflect your true concurrency availability. This is because Lambda also considers reserved concurrency and provisioned concurrency to determine availability.

To illustrate ClaimedAccountConcurrency, consider a scenario where you configure a lot of reserved concurrency and provisioned concurrency across your functions that go largely unused. In the following example, assume that your account concurrency limit is 1,000, and you have two main functions in your account: function-orange and function-blue. You allocate 600 units of reserved concurrency for function-orange. You allocate 200 units of provisioned concurrency for function-blue. Suppose that over time, you deploy additional functions and observe the following traffic pattern:

In the previous diagram, the black lines indicate the actual concurrency use over time, and the red line indicates the value of `ClaimedAccountConcurrency` over time. Throughout this scenario, `ClaimedAccountConcurrency` is 800 at minimum, despite low actual concurrency utilization across your functions. This is because you allocated 800 total units of concurrency for function-orange and function-blue. From Lambda's perspective, you have "claimed" this concurrency for use, so you effectively have only 200 units of concurrency remaining for other functions.

For this scenario, allocated concurrency is 800 in the `ClaimedAccountConcurrency` formula. We can then derive the value of `ClaimedAccountConcurrency` at various points in the diagram:

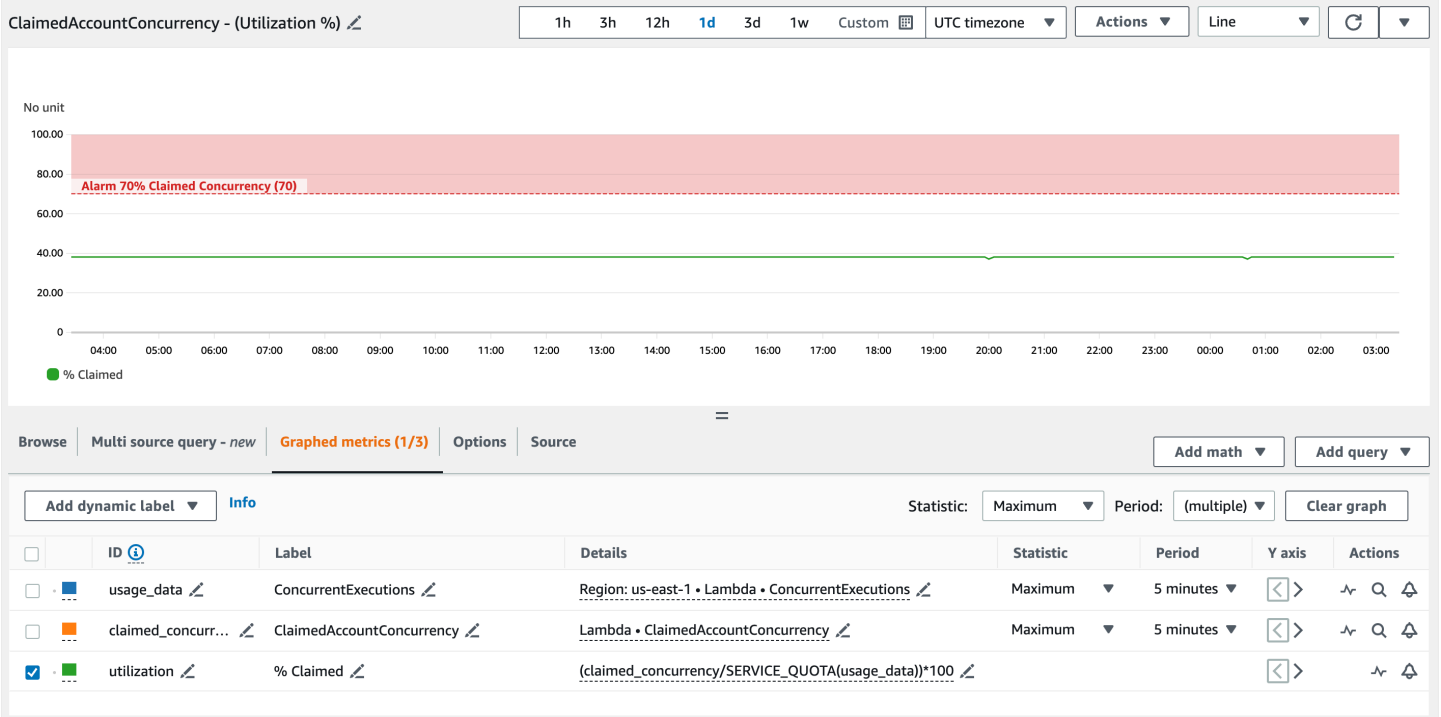

- At t1, `ClaimedAccountConcurrency` is 800 ($800 + 0$ `UnreservedConcurrentExecutions`).
- At t2, `ClaimedAccountConcurrency` is 900 ($800 + 100$ `UnreservedConcurrentExecutions`).
- At t3, `ClaimedAccountConcurrency` is again 900 ($800 + 100$ `UnreservedConcurrentExecutions`).

Setting up the ClaimedAccountConcurrency metric in CloudWatch

Lambda emits the ClaimedAccountConcurrency metric in CloudWatch. Use this metric along with the value of SERVICE_QUOTA(ConcurrentExecutions) to get the percent utilization of concurrency in your account, as shown in the following formula:

Utilization = (ClaimedAccountConcurrency/SERVICE_QUOTA(ConcurrentExecutions)) * 100%

The following screenshot illustrates how you can graph this formula in CloudWatch. The green claim_utilization line represents the concurrency utilization in this account, which is at around 40%:

The previous screenshot also includes a CloudWatch alarm that goes into ALARM state when the concurrency utilization exceeds 70%. You can use the ClaimedAccountConcurrency metric along with similar alarms to proactively determine when you might need to request a higher account concurrency limit.

Building Lambda functions with Node.js

You can run JavaScript code with Node.js in AWS Lambda. Lambda provides [runtimes](#) for Node.js that run your code to process events. Your code runs in an environment that includes the AWS SDK for JavaScript, with credentials from an AWS Identity and Access Management (IAM) role that you manage. To learn more about the SDK versions included with the Node.js runtimes, see [the section called “Runtime-included SDK versions”](#).

Lambda supports the following Node.js runtimes.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
Node.js 24	nodejs24.x	Amazon Linux 2023	Apr 30, 2028	Jun 1, 2028	Jul 1, 2028
Node.js 22	nodejs22.x	Amazon Linux 2023	Apr 30, 2027	Jun 1, 2027	Jul 1, 2027
Node.js 20	nodejs20.x	Amazon Linux 2023	Apr 30, 2026	Aug 31, 2026	Sep 30, 2026

To create a Node.js function

1. Open the [Lambda console](#).
2. Choose **Create function**.
3. Configure the following settings:
 - **Function name:** Enter a name for the function.
 - **Runtime:** Choose **Node.js 24.x**.
4. Choose **Create function**.

The console creates a Lambda function with a single source file named `index.mjs`. You can edit this file and add more files in the built-in code editor. In the **DEPLOY** section, choose **Deploy** to

update your function's code. Then, to run your code, choose **Create test event** in the **TEST EVENTS** section.

The `index.mjs` file exports a function named `handler` that takes an event object and a context object. This is the [handler function](#) that Lambda calls when the function is invoked. The Node.js function runtime gets invocation events from Lambda and passes them to the handler. In the function configuration, the handler value is `index.handler`.

When you save your function code, the Lambda console creates a .zip file archive deployment package. When you develop your function code outside of the console (using an IDE) you need to [create a deployment package](#) to upload your code to the Lambda function.

The function runtime passes a context object to the handler, in addition to the invocation event. The [context object](#) contains additional information about the invocation, the function, and the execution environment. More information is available from environment variables.

Your Lambda function comes with a CloudWatch Logs log group. The function runtime sends details about each invocation to CloudWatch Logs. It relays any [logs that your function outputs](#) during invocation. If your function returns an error, Lambda formats the error and returns it to the invoker.

Runtime-included SDK versions

All [supported Lambda Node.js runtimes](#) include a specific minor version of the AWS SDK for JavaScript v3, not the [latest version](#). The specific minor version that's included in the runtime depends on the runtime version and your AWS Region. To find the specific version of the SDK included in the runtime that you're using, create a Lambda function with the following code.

Example index.mjs

```
import packageJson from '@aws-sdk/client-s3/package.json' with { type: 'json' };

export const handler = async () => ({ version: packageJson.version });
```

This returns a response in the following format:

```
{
  "version": "3.632.0"
}
```

For more information, see [Using the SDK for JavaScript v3 in your handler](#).

Using keep-alive for TCP connections

The default Node.js HTTP/HTTPS agent creates a new TCP connection for every new request. To avoid the cost of establishing new connections, keep-alive is enabled by default in all [supported Node.js runtimes](#). Keep-alive can reduce request times for Lambda functions that make multiple API calls using the SDK.

To disable keep-alive, see [Reusing connections with keep-alive in Node.js](#) in the *AWS SDK for JavaScript 3.x Developer Guide*. For more information about using keep-alive, see [HTTP keep-alive is on by default in modular AWS SDK for JavaScript](#) on the AWS Developer Tools Blog.

CA certificate loading

For Node.js runtime versions up to Node.js 18, Lambda automatically loads Amazon-specific CA (certificate authority) certificates to make it easier for you to create functions that interact with other AWS services. For example, Lambda includes the Amazon RDS certificates necessary for

validating the [server identity certificate](#) installed on your Amazon RDS database. This behavior can have a performance impact during cold starts.

Starting with Node.js 20, Lambda no longer loads additional CA certificates by default. The Node.js 20 runtime contains a certificate file with all Amazon CA certificates located at `/var/runtime/ca-cert.pem`. To restore the same behavior from Node.js 18 and earlier runtimes, set the `NODE_EXTRA_CA_CERTS` [environment variable](#) to `/var/runtime/ca-cert.pem`.

For optimal performance, we recommend bundling only the certificates that you need with your deployment package and loading them via the `NODE_EXTRA_CA_CERTS` environment variable. The certificates file should consist of one or more trusted root or intermediate CA certificates in PEM format. For example, for RDS, include the required certificates alongside your code as `certificates/rds.pem`. Then, load the certificates by setting `NODE_EXTRA_CA_CERTS` to `/var/task/certificates/rds.pem`.

Experimental Node.js features

The upstream Node.js language releases enable some experimental features by default. Lambda disables these features to ensure runtime stability and consistent performance. The following table lists the experimental features that Lambda disables.

Experimental feature	Supported Node.js versions	Node.js flag applied by Lambda	Lambda flag to re-enable
Support for importing modules using <code>require</code> in ES modules	Node.js 20, Node.js 22	<code>--no-experimental-require-module</code>	<code>--experimental-require-module</code>
Support for automatically detecting ES vs CommonJS modules	Node.js 22	<code>--no-experimental-detect-module</code>	<code>--experimental-detect-module</code>

To enable a disabled experimental feature, set the re-enable flag in the `NODE_OPTIONS` environment variable. For example, to enable ES module `require` support, set `NODE_OPTIONS` to `--`

`experimental-require-module`. Lambda detects this override and removes the corresponding disable flag.

 **Important**

Using experimental features can lead to instability and performance issues. These features might be changed or removed in future Node.js versions. Functions that use experimental features aren't eligible for the Lambda Service Level Agreement (SLA) or AWS Support.

Define Lambda function handler in Node.js

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in Node.js, including options for project setup, naming conventions, and best practices. This page also includes an example of a Node.js Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (Amazon S3) bucket. For information about how to deploy your function after writing it, see [the section called “Deploy .zip file archives”](#) or [the section called “Deploy container images”](#).

Setting up your Node.js handler project

There are multiple ways to initialize a Node.js Lambda project. For example, you can create a standard Node.js project using npm, create an [AWS SAM application](#), or create an [AWS CDK application](#).

To create the project using npm:

```
npm init
```

This command initializes your project and generates a `package.json` file that manages your project's metadata and dependencies.

Your function code lives in a `.js` or `.mjs` JavaScript file. In the following example, we name this file `index.mjs` because it uses an ES module handler. Lambda supports both ES module and CommonJS handlers. For more information, see [CommonJS and ES Modules](#).

A typical Node.js Lambda function project follows this general structure:

```
/project-root
  ### index.mjs – Contains main handler
  ### package.json – Project metadata and dependencies
  ### package-lock.json – Dependency lock file
  ### node_modules/ – Installed dependencies
```

Example Node.js Lambda function code

The following example Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket.

Example `index.mjs` Lambda function

```
import { S3Client, PutObjectCommand } from '@aws-sdk/client-s3';

// Initialize the S3 client outside the handler for reuse
const s3Client = new S3Client();

/**
 * Lambda handler for processing orders and storing receipts in S3.
 * @param {Object} event - Input event containing order details
 * @param {string} event.order_id - The unique identifier for the order
 * @param {number} event.amount - The order amount
 * @param {string} event.item - The item purchased
 * @returns {Promise<string>} Success message
 */
export const handler = async(event) => {
  try {
    // Access environment variables
    const bucketName = process.env.RECEIPT_BUCKET;
    if (!bucketName) {
      throw new Error('RECEIPT_BUCKET environment variable is not set');
    }
  }
}
```

```

        // Create the receipt content and key destination
        const receiptContent = `OrderID: ${event.order_id}\nAmount: $
${event.amount.toFixed(2)}\nItem: ${event.item}`;
        const key = `receipts/${event.order_id}.txt`;

        // Upload the receipt to S3
        await uploadReceiptToS3(bucketName, key, receiptContent);

        console.log(`Successfully processed order ${event.order_id} and stored receipt
in S3 bucket ${bucketName}`);
        return 'Success';
    } catch (error) {
        console.error(`Failed to process order: ${error.message}`);
        throw error;
    }
};

/**
 * Helper function to upload receipt to S3
 * @param {string} bucketName - The S3 bucket name
 * @param {string} key - The S3 object key
 * @param {string} receiptContent - The content to upload
 * @returns {Promise<void>}
 */
async function uploadReceiptToS3(bucketName, key, receiptContent) {
    try {
        const command = new PutObjectCommand({
            Bucket: bucketName,
            Key: key,
            Body: receiptContent
        });

        await s3Client.send(command);
    } catch (error) {
        throw new Error(`Failed to upload receipt to S3: ${error.message}`);
    }
}

```

This `index.mjs` file contains the following sections of code:

- **import block:** Use this block to include libraries that your Lambda function requires, such as [AWS SDK clients](#).

- `const s3Client` declaration: This initializes an [Amazon S3 client](#) outside of the handler function. This causes Lambda to run this code during the [initialization phase](#), and the client is preserved for [reuse across multiple invocations](#).
- JSDoc comment block: Define the input and output types for your handler using [JSDoc annotations](#).
- `export const handler`: This is the main handler function that Lambda invokes. When deploying your function, specify `index.handler` for the [Handler](#) property. The value of the `Handler` property is the file name and the name of the exported handler method, separated by a dot.
- `uploadReceiptToS3` function: This is a helper function that's referenced by the main handler function.

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

CommonJS and ES Modules

Node.js supports two module systems: CommonJS and ECMAScript modules (ES modules). Lambda recommends using ES modules as it supports top-level `await`, which enables asynchronous tasks to be completed during [execution environment initialization](#).

Node.js treats files with a `.cjs` file name extension as CommonJS modules while a `.mjs` extension denotes ES modules. By default, Node.js treats files with the `.js` file name extension as CommonJS modules. You can configure Node.js to treat `.js` files as ES modules by specifying the type as `module` in the function's `package.json` file. You can configure Node.js in Lambda to detect automatically whether a `.js` file should be treated as CommonJS or as an ES module by adding the `--experimental-detect-module` flag to the `NODE_OPTIONS` environment variable. For more information, see [Experimental Node.js features](#).

The following examples show function handlers written using both ES modules and CommonJS modules. The remaining examples on this page all use ES modules.

ES module example

Example – ES module handler

```
const url = "https://aws.amazon.com/";
```

```
export const handler = async(event) => {
  try {
    const res = await fetch(url);
    console.info("status", res.status);
    return res.status;
  }
  catch (e) {
    console.error(e);
    return 500;
  }
};
```

CommonJS module example

Example – CommonJS module handler

```
const https = require("https");
let url = "https://aws.amazon.com/";

exports.handler = async function (event) {
  let statusCode;
  await new Promise(function (resolve, reject) {
    https.get(url, (res) => {
      statusCode = res.statusCode;
      resolve(statusCode);
    }).on("error", (e) => {
      reject(Error(e));
    });
  });
  console.log(statusCode);
  return statusCode;
};
```

Node.js initialization

Node.js uses a non-blocking I/O model that supports efficient asynchronous operations using an event loop. For example, if Node.js makes a network call, the function continues to process other operations without blocking on a network response. When the network response is received, it is placed into the callback queue. Tasks from the queue are processed when the current task completes.

Lambda recommends using top-level `await` so that asynchronous tasks initiated during execution environment initialization are completed during initialization. Asynchronous tasks that are not completed during initialization will typically run during the first function invoke. This can cause unexpected behavior or errors. For example, your function initialization may make a network call to fetch a parameter from AWS Parameter Store. If this task is not completed during initialization, the value may be null during an invocation. There can also be a delay between initialization and invoke which can trigger errors in time-sensitive operations. In particular, AWS service calls can rely on time-sensitive request signatures, resulting in service call failures if the call is not completed during the initialization phase. Completing tasks during initialization typically improves cold-start performance, and first invoke performance when using Provisioned Concurrency. For more information, see our blog post [Using Node.js ES modules and top-level await in AWS Lambda](#).

Handler naming conventions

When you configure a function, the value of the [Handler](#) setting is the file name and the name of the exported handler method, separated by a dot. The default for functions created in the console and for examples in this guide is `index.handler`. This indicates the `handler` method that's exported from the `index.js` or `index.mjs` file.

If you create a function in the console using a different file name or function handler name, you must edit the default handler name.

To change the function handler name (console)

1. Open the [Functions](#) page of the Lambda console and choose your function.
2. Choose the **Code** tab.
3. Scroll down to the **Runtime settings** pane and choose **Edit**.
4. In **Handler**, enter the new name for your function handler.
5. Choose **Save**.

Defining and accessing the input event object

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "order_id": "12345",
```

```
"amount": 199.99,  
"item": "Wireless Headphones"  
}
```

When working with Lambda functions in Node.js, you can define the expected shape of the input event using JSDoc annotations. In this example, we define the input structure in the handler's JSDoc comment:

```
/**  
 * Lambda handler for processing orders and storing receipts in S3.  
 * @param {Object} event - Input event containing order details  
 * @param {string} event.order_id - The unique identifier for the order  
 * @param {number} event.amount - The order amount  
 * @param {string} event.item - The item purchased  
 * @returns {Promise<string>} Success message  
 */
```

After you define these types in your JSDoc comment, you can access the fields of the event object directly in your code. For example, `event.order_id` retrieves the value of `order_id` from the original input.

Valid handler patterns for Node.js functions

We recommend that you use [async/await](#) to declare the function handler instead of using [callbacks](#). Async/await is a concise and readable way to write asynchronous code, without the need for nested callbacks or chaining promises. With async/await, you can write code that reads like synchronous code, while still being asynchronous and non-blocking.

async function handlers (recommended)

The `async` keyword marks a function as asynchronous, and the `await` keyword pauses the execution of the function until a Promise is resolved. The handler accepts the following arguments:

- **event**: Contains the input data passed to your function.
- **context**: Contains information about the invocation, function, and execution environment. For more information, see [Using the Lambda context object to retrieve Node.js function information](#).

Here are the valid signatures for the async/await pattern:

```
export const handler = async (event) => { };
```

```
export const handler = async (event, context) => { };
```

Synchronous function handlers

Where your function does not perform any asynchronous tasks, you can use a synchronous function handler, using one of the following function signatures:

```
export const handler = (event) => { };
```

```
export const handler = (event, context) => { };
```

Response streaming function handlers

Lambda supports response streaming with Node.js. Response streaming function handlers use the `awslambda.streamifyResponse()` decorator and take 3 parameters: `event`, `responseStream`, and `context`. The function signature is:

```
export const handler = awslambda.streamifyResponse(async (event, responseStream,  
context) => { });
```

For more information, see [Response streaming for Lambda functions](#).

Callback-based function handlers

Note

Callback-based function handlers are only supported up to Node.js 22. Starting from Node.js 24, asynchronous tasks should be implemented using async function handlers.

Callback-based function handlers must use the `event`, `context`, and `callback` arguments. Example:

```
export const handler = (event, context, callback) => { };
```

The callback function expects an `Error` and a response, which must be JSON-serializable. The function continues to execute until the [event loop](#) is empty or the function times out. The response

isn't sent to the invoker until all event loop tasks are finished. If the function times out, an error is returned instead. You can configure the runtime to send the response immediately by setting [context.callbackWaitsForEmptyEventLoop](#) to false.

Example – HTTP request with callback

The following example function checks a URL and returns the status code to the invoker.

```
import https from "https";
let url = "https://aws.amazon.com/";

export const handler = (event, context, callback) => {
  https.get(url, (res) => {
    callback(null, res.statusCode);
  }).on("error", (e) => {
    callback(Error(e));
  });
};
```

Using the SDK for JavaScript v3 in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the AWS SDK for JavaScript. All [supported Lambda Node.js runtimes](#) include the [SDK for JavaScript version 3](#). However, we strongly recommend that you include the AWS SDK clients that you need in your deployment package. This maximizes [backward compatibility](#) during future Lambda runtime updates. Only rely on the runtime-provided SDK when you can't include additional packages (for example, when using the Lambda console code editor or inline code in an AWS CloudFormation template).

To add SDK dependencies to your function, use the `npm install` command for the specific SDK clients that you need. In the example code, we used the [Amazon S3 client](#). Add this dependency by running the following command in the directory that contains your `package.json` file:

```
npm install @aws-sdk/client-s3
```

In the function code, import the client and commands that you need, as the example function demonstrates:

```
import { S3Client, PutObjectCommand } from '@aws-sdk/client-s3';
```

Then, initialize an [Amazon S3 client](#):

```
const s3Client = new S3Client();
```

In this example, we initialized our Amazon S3 client outside of the main handler function to avoid having to initialize it every time we invoke our function. After you initialize your SDK client, you can then use it to make API calls for that AWS service. The example code calls the Amazon S3 [PutObject](#) API action as follows:

```
const command = new PutObjectCommand({  
  Bucket: bucketName,  
  Key: key,  
  Body: receiptContent  
});
```

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using `process.env`. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following lines of code:

```
// Access environment variables  
const bucketName = process.env.RECEIPT_BUCKET;  
if (!bucketName) {  
  throw new Error('RECEIPT_BUCKET environment variable is not set');  
}
```

Using global state

Lambda runs your static code during the [initialization phase](#) before invoking your function for the first time. Resources created during initialization stay in memory between invocations, so you can avoid having to create them every time you invoke your function.

In the example code, the S3 client initialization code is outside the handler. The runtime initializes the client before the function handles its first event, and the client remains available for reuse across all invocations.

Code best practices for Node.js Lambda functions

Follow these guidelines when building Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. For the Node.js and Python runtimes, these include the AWS SDKs. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation.

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the

function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Deploy Node.js Lambda functions with .zip file archives

Your AWS Lambda function's code comprises a .js or .mjs file containing your function's handler code, together with any additional packages and modules your code depends on. To deploy this function code to Lambda, you use a *deployment package*. This package may either be a .zip file archive or a container image. For more information about using container images with Node.js, see [Deploy Node.js Lambda functions with container images](#).

To create your deployment package as .zip file archive, you can use your command-line tool's built-in .zip file archive utility, or any other .zip file utility such as [7zip](#). The examples shown in the following sections assume you're using a command-line zip tool in a Linux or MacOS environment. To use the same commands in Windows, you can [install the Windows Subsystem for Linux](#) to get a Windows-integrated version of Ubuntu and Bash.

Note that Lambda uses POSIX file permissions, so you may need to [set permissions for the deployment package folder](#) before you create the .zip file archive.

Topics

- [Runtime dependencies in Node.js](#)
- [Creating a .zip deployment package with no dependencies](#)
- [Creating a .zip deployment package with dependencies](#)
- [Creating a Node.js layer for your dependencies](#)
- [Dependency search path and runtime-included libraries](#)
- [Creating and updating Node.js Lambda functions using .zip files](#)

Runtime dependencies in Node.js

For Lambda functions that use the Node.js runtime, a dependency can be any Node.js module. The Node.js runtime includes a number of common libraries, as well as a version of the AWS SDK for JavaScript. All [supported Node.js runtimes](#) include version 3 of the SDK. To use version 2 of the SDK, you must add the SDK to your .zip file deployment package. To find the specific version of the SDK that's included in the runtime that you're using, see [the section called "Runtime-included SDK versions"](#).

Lambda periodically updates the SDK libraries in the Node.js runtime to include the latest features and security upgrades. Lambda also applies security patches and updates to the other libraries

included in the runtime. To have full control of the dependencies in your package, you can add your preferred version of any runtime-included dependency to your deployment package. For example, if you want to use a particular version of the SDK for JavaScript, you can include it in your .zip file as a dependency. For more information on adding runtime-included dependencies to your .zip file, see [Dependency search path and runtime-included libraries](#).

Under the [AWS shared responsibility model](#), you are responsible for the management of any dependencies in your functions' deployment packages. This includes applying updates and security patches. To update dependencies in your function's deployment package, first create a new .zip file and then upload it to Lambda. See [Creating a .zip deployment package with dependencies](#) and [Creating and updating Node.js Lambda functions using .zip files](#) for more information.

Creating a .zip deployment package with no dependencies

If your function code has no dependencies except for libraries included in the Lambda runtime, your .zip file contains only the `index.js` or `index.mjs` file with your function's handler code. Use your preferred zip utility to create a .zip file with your `index.js` or `index.mjs` file at the root. If the file containing your handler code isn't at the root of your .zip file, Lambda won't be able to run your code.

To learn how to deploy your .zip file to create a new Lambda function or update an existing one, see [Creating and updating Node.js Lambda functions using .zip files](#).

Creating a .zip deployment package with dependencies

If your function code depends on packages or modules that aren't included in the Lambda Node.js runtime, you can either add these dependencies to your .zip file with your function code or use a [Lambda layer](#). The instructions in this section show you how to include your dependencies in your .zip deployment package. For instructions on how to include your dependencies in a layer, see [the section called "Creating a Node.js layer for your dependencies"](#).

The following example CLI commands create a .zip file named `my_deployment_package.zip` containing the `index.js` or `index.mjs` file with your function's handler code and its dependencies. In the example, you install dependencies using the npm package manager.

To create the deployment package

1. Navigate to the project directory containing your `index.js` or `index.mjs` source code file. In this example, the directory is named `my_function`.

```
cd my_function
```

2. Install your function's required libraries in the `node_modules` directory using the `npm install` command. In this example you install the AWS X-Ray SDK for Node.js.

```
npm install aws-xray-sdk
```

This creates a folder structure similar to the following:

```
~/my_function
### index.mjs
### node_modules
    ### async
    ### async-listener
    ### atomic-batcher
    ### aws-sdk
    ### aws-xray-sdk
    ### aws-xray-sdk-core
```

You can also add custom modules that you create yourself to your deployment package. Create a directory under `node_modules` with the name of your module and save your custom written packages there.

3. Create a `.zip` file that contains the contents of your project folder at the root. Use the `r` (recursive) option to ensure that zip compresses the subfolders.

```
zip -r my_deployment_package.zip .
```

Creating a Node.js layer for your dependencies

The instructions in this section show you how to include your dependencies in a layer. For instructions on how to include your dependencies in your deployment package, see [the section called "Creating a .zip deployment package with dependencies"](#).

When you add a layer to a function, Lambda loads the layer content into the `/opt` directory of that execution environment. For each Lambda runtime, the `PATH` variable already includes specific folder paths within the `/opt` directory. To ensure that Lambda picks up your layer content, your layer `.zip` file should have its dependencies in one of the following folder paths:

- nodejs/node_modules
- nodejs/node18/node_modules (NODE_PATH)
- nodejs/node20/node_modules (NODE_PATH)
- nodejs/node22/node_modules (NODE_PATH)

For example, your layer .zip file structure might look like the following:

```
xray-sdk.zip
# nodejs/node_modules/aws-xray-sdk
```

In addition, Lambda automatically detects any libraries in the /opt/lib directory, and any binaries in the /opt/bin directory. To ensure that Lambda properly finds your layer content, you can also create a layer with the following structure:

```
custom-layer.zip
# lib
| lib_1
| lib_2
# bin
| bin_1
| bin_2
```

After you package your layer, see [the section called “Creating and deleting layers”](#) and [the section called “Adding layers”](#) to complete your layer setup.

Dependency search path and runtime-included libraries

The Node.js runtime includes a number of common libraries, as well as a version of the AWS SDK for JavaScript. If you want to use a different version of a runtime-included library, you can do this by bundling it with your function or by adding it as a dependency in your deployment package. For example, you can use a different version of the SDK by adding it to your .zip deployment package. You can also include it in a [Lambda layer](#) for your function.

When you use an `import` or `require` statement in your code, the Node.js runtime searches the directories in the `NODE_PATH` path until it finds the module. By default, the first location the runtime searches is the directory into which your .zip deployment package is decompressed and mounted (`/var/task`). If you include a version of a runtime-included library in your deployment

package, this version will take precedence over the version included in the runtime. Dependencies in your deployment package also have precedence over dependencies in layers.

When you add a dependency to a layer, Lambda extracts this to `/opt/nodejs/nodexx/node_modules` where `nodexx` represents the version of the runtime you are using. In the search path, this directory has precedence over the directory containing the runtime-included libraries (`/var/lang/lib/node_modules`). Libraries in function layers therefore have precedence over versions included in the runtime.

You can see the full search path for your Lambda function by adding the following line of code.

```
console.log(process.env.NODE_PATH)
```

You can also add dependencies in a separate folder inside your `.zip` package. For example, you might add a custom module to a folder in your `.zip` package called `common`. When your `.zip` package is decompressed and mounted, this folder is placed inside the `/var/task` directory. To use a dependency from a folder in your `.zip` deployment package in your code, use an `import { } from` or `const { } = require()` statement, depending on whether you are using CJS or ESM module resolution. For example:

```
import { myModule } from './common'
```

If you bundle your code with `esbuild`, `rollup`, or similar, the dependencies used by your function are bundled together in one or more files. We recommend using this method to vend dependencies whenever possible. Compared to adding dependencies to your deployment package, bundling your code results in improved performance due to the reduction in I/O operations.

Creating and updating Node.js Lambda functions using .zip files

After you have created your `.zip` deployment package, you can use it to create a new Lambda function or update an existing one. You can deploy your `.zip` package using the Lambda console, the AWS Command Line Interface, and the Lambda API. You can also create and update Lambda functions using AWS Serverless Application Model (AWS SAM) and CloudFormation.

The maximum size for a `.zip` deployment package for Lambda is 250 MB (unzipped). Note that this limit applies to the combined size of all the files you upload, including any Lambda layers.

The Lambda runtime needs permission to read the files in your deployment package. In Linux permissions octal notation, Lambda needs 644 permissions for non-executable files (rw-r--r--) and 755 permissions (rwxr-xr-x) for directories and executable files.

In Linux and MacOS, use the `chmod` command to change file permissions on files and directories in your deployment package. For example, to give a non-executable file the correct permissions, run the following command.

```
chmod 644 <filepath>
```

To change file permissions in Windows, see [Set, View, Change, or Remove Permissions on an Object](#) in the Microsoft Windows documentation.

Note

If you don't grant Lambda the permissions it needs to access directories in your deployment package, Lambda sets the permissions for those directories to 755 (rwxr-xr-x).

Creating and updating functions with .zip files using the console

To create a new function, you must first create the function in the console, then upload your .zip archive. To update an existing function, open the page for your function, then follow the same procedure to add your updated .zip file.

If your .zip file is less than 50MB, you can create or update a function by uploading the file directly from your local machine. For .zip files greater than 50MB, you must upload your package to an Amazon S3 bucket first. For instructions on how to upload a file to an Amazon S3 bucket using the AWS Management Console, see [Getting started with Amazon S3](#). To upload files using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

To create a new function (console)

1. Open the [Functions page](#) of the Lambda console and choose **Create Function**.
2. Choose **Author from scratch**.
3. Under **Basic information**, do the following:
 - a. For **Function name**, enter the name for your function.
 - b. For **Runtime**, select the runtime you want to use.
 - c. (Optional) For **Architecture**, choose the instruction set architecture for your function. The default architecture is x86_64. Ensure that the .zip deployment package for your function is compatible with the instruction set architecture you select.
4. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing one.
5. Choose **Create function**. Lambda creates a basic 'Hello world' function using your chosen runtime.

To upload a .zip archive from your local machine (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload the .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip file**.
5. To upload the .zip file, do the following:
 - a. Select **Upload**, then select your .zip file in the file chooser.
 - b. Choose **Open**.
 - c. Choose **Save**.

To upload a .zip archive from an Amazon S3 bucket (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload a new .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.

4. Choose **Amazon S3 location**.
5. Paste the Amazon S3 link URL of your .zip file and choose **Save**.

Updating .zip file functions using the console code editor

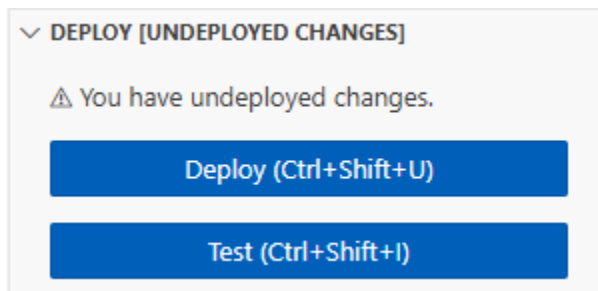

For some functions with .zip deployment packages, you can use the Lambda console's built-in code editor to update your function code directly. To use this feature, your function must meet the following criteria:

- Your function must use one of the interpreted language runtimes (Python, Node.js, or Ruby)
- Your function's deployment package must be smaller than 50 MB (unzipped).

Function code for functions with container image deployment packages cannot be edited directly in the console.

To update function code using the console code editor

1. Open the [Functions page](#) of the Lambda console and select your function.
2. Select the **Code** tab.
3. In the **Code source** pane, select your source code file and edit it in the integrated code editor.
4. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Creating and updating functions with .zip files using the AWS CLI

You can use the [AWS CLI](#) to create a new function or to update an existing one using a .zip file. Use the [create-function](#) and [update-function-code](#) commands to deploy your .zip package. If your .zip file is smaller than 50MB, you can upload the .zip package from a file location on your local build machine. For larger files, you must upload your .zip package from an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

If you upload your .zip file from an Amazon S3 bucket using the AWS CLI, the bucket must be located in the same AWS Region as your function.

To create a new function using a .zip file with the AWS CLI, you must specify the following:

- The name of your function (`--function-name`)
- Your function's runtime (`--runtime`)
- The Amazon Resource Name (ARN) of your function's [execution role](#) (`--role`)
- The name of the handler method in your function code (`--handler`)

You must also specify the location of your .zip file. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda create-function --function-name myFunction \  
--runtime nodejs24.x --handler index.handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--code` option as shown in the following example command. You only need to use the `S3ObjectVersion` parameter for versioned objects.

```
aws lambda create-function --function-name myFunction \  
--runtime nodejs24.x --handler index.handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--code S3Bucket=amzn-s3-demo-  
bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion
```

To update an existing function using the CLI, you specify the the name of your function using the `--function-name` parameter. You must also specify the location of the .zip file you want to use to update your function code. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda update-function-code --function-name myFunction \  
--zip-file fileb://myFunction.zip
```

```
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--s3-bucket` and `--s3-key` options as shown in the following example command. You only need to use the `--s3-object-version` parameter for versioned objects.

```
aws lambda update-function-code --function-name myFunction \  
--s3-bucket amzn-s3-demo-bucket --s3-key myFileName.zip --s3-object-version myObject  
Version
```

Creating and updating functions with .zip files using the Lambda API

To create and update functions using a .zip file archive, use the following API operations:

- [CreateFunction](#)
- [UpdateFunctionCode](#)

Creating and updating functions with .zip files using AWS SAM

The AWS Serverless Application Model (AWS SAM) is a toolkit that helps streamline the process of building and running serverless applications on AWS. You define the resources for your application in a YAML or JSON template and use the AWS SAM command line interface (AWS SAM CLI) to build, package, and deploy your applications. When you build a Lambda function from an AWS SAM template, AWS SAM automatically creates a .zip deployment package or container image with your function code and any dependencies you specify. To learn more about using AWS SAM to build and deploy Lambda functions, see [Getting started with AWS SAM](#) in the *AWS Serverless Application Model Developer Guide*.

You can also use AWS SAM to create a Lambda function using an existing .zip file archive. To create a Lambda function using AWS SAM, you can save your .zip file in an Amazon S3 bucket or in a local folder on your build machine. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your AWS SAM template, the `AWS::Serverless::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - set to `Zip`
- `CodeUri` - set to the function code's Amazon S3 URI, path to local folder, or [FunctionCode](#) object
- `Runtime` - Set to your chosen runtime

With AWS SAM, if your .zip file is larger than 50MB, you don't need to upload it to an Amazon S3 bucket first. AWS SAM can upload .zip packages up to the maximum allowed size of 250MB (unzipped) from a location on your local build machine.

To learn more about deploying functions using .zip file in AWS SAM, see [AWS::Serverless::Function](#) in the *AWS SAM Developer Guide*.

Creating and updating functions with .zip files using CloudFormation

You can use CloudFormation to create a Lambda function using a .zip file archive. To create a Lambda function from a .zip file, you must first upload your file to an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your CloudFormation template, the `AWS::Lambda::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - Set to `Zip`
- `Code` - Enter the Amazon S3 bucket name and the .zip file name in the `S3Bucket` and `S3Key` fields
- `Runtime` - Set to your chosen runtime

The .zip file that CloudFormation generates cannot exceed 4MB. To learn more about deploying functions using .zip file in CloudFormation, see [AWS::Lambda::Function](#) in the *CloudFormation User Guide*.

Deploy Node.js Lambda functions with container images

There are three ways to build a container image for a Node.js Lambda function:

- [Using an AWS base image for Node.js](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include the [runtime interface client for Node.js](#) in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the [runtime interface client for Node.js](#) in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

Topics

- [AWS base images for Node.js](#)
- [Using an AWS base image for Node.js](#)
- [Using an alternative base image with the runtime interface client](#)

AWS base images for Node.js

AWS provides the following base images for Node.js:

Tags	Runtime	Operating system	Dockerfile	Deprecation
24	Node.js 24	Amazon Linux 2023	Dockerfile for Node.js 24 on GitHub	Apr 30, 2028
22	Node.js 22	Amazon Linux 2023	Dockerfile for Node.js 22 on GitHub	Apr 30, 2027
20	Node.js 20	Amazon Linux 2023	Dockerfile for Node.js 20 on GitHub	Apr 30, 2026

Amazon ECR repository: gallery.ecr.aws/lambda/nodejs

The Node.js 20 and later base images are based on the [Amazon Linux 2023 minimal container image](#). Earlier base images use Amazon Linux 2. AL2023 provides several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as glibc.

AL2023-based images use microdnf (symlinked as dnf) as the package manager instead of yum, which is the default package manager in Amazon Linux 2. microdnf is a standalone implementation of dnf. For a list of packages that are included in AL2023-based images, refer to the **Minimal Container** columns in [Comparing packages installed on Amazon Linux 2023 Container Images](#). For more information about the differences between AL2023 and Amazon Linux 2, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

Note

To run AL2023-based images locally, including with AWS Serverless Application Model (AWS SAM), you must use Docker version 20.10.10 or later.

Using an AWS base image for Node.js

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Node.js

Creating an image from a base image

To create a container image from an AWS base image for Node.js

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new Node.js project with npm. To accept the default options provided in the interactive experience, press Enter.

```
npm init
```

3. Create a new file called `index.js`. You can add the following sample function code to the file for testing, or use your own.

Example CommonJS handler

```
exports.handler = async (event) => {
  const response = {
    statusCode: 200,
    body: JSON.stringify('Hello from Lambda!'),
  };
  return response;
};
```

4. If your function depends on libraries other than the AWS SDK for JavaScript, use [npm](#) to add them to your package.

5. Create a new Dockerfile with the following configuration:

- Set the FROM property to the [URI of the base image](#).
- Use the COPY command to copy the function code and runtime dependencies to `{LAMBDA_TASK_ROOT}`, a [Lambda-defined environment variable](#).
- Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/nodejs:22

# Copy function code
COPY index.js ${LAMBDA_TASK_ROOT}

# Set the CMD to your handler (could also be done as a parameter override outside
  of the Dockerfile)
CMD [ "index.handler" ]
```

6. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

1. Start the Docker image with the **docker run** command. In this example, `docker-image` is the image name and `test` is the tag.

```
docker run --platform linux/amd64 -p 9000:8080 docker-image:test
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

2. From a new terminal window, post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType "application/json"
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Using an alternative base image with the runtime interface client

If you use an [OS-only base image](#) or an alternative base image, you must include the runtime interface client in your image. The runtime interface client extends the [Runtime API](#), which manages the interaction between Lambda and your function code.

Install the [Node.js runtime interface client](#) using the npm package manager:

```
npm install aws-lambda-ric
```

You can also download the [Node.js runtime interface client](#) from GitHub.

The following example demonstrates how to build a container image for Node.js using a non-AWS base image. The example Dockerfile uses a bookworm base image. The Dockerfile includes the runtime interface client.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).

- Node.js

Creating an image from an alternative base image

To create a container image from a non-AWS base image

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new Node.js project with npm. To accept the default options provided in the interactive experience, press Enter.

```
npm init
```

3. Create a new file called `index.js`. You can add the following sample function code to the file for testing, or use your own.

```
exports.handler = async (event) => {
  const response = {
    statusCode: 200,
    body: JSON.stringify('Hello from Lambda!'),
  };
  return response;
};
```

4. Create a new Dockerfile. The following Dockerfile uses a bookworm base image instead of an [AWS base image](#). The Dockerfile includes the [runtime interface client](#), which makes the image compatible with Lambda. The Dockerfile uses a [multi-stage build](#). The first stage creates a build image, which is a standard Node.js environment where the function's dependencies are installed. The second stage creates a slimmer image which includes the function code and its dependencies. This reduces the final image size.

- Set the FROM property to the base image identifier.
- Use the COPY command to copy the function code and runtime dependencies.
- Set the ENTRYPOINT to the module that you want the Docker container to run when it starts. In this case, the module is the runtime interface client.

- Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
# Define custom function directory
ARG FUNCTION_DIR="/function"

FROM node:20-bookworm as build-image

# Include global arg in this stage of the build
ARG FUNCTION_DIR

# Install build dependencies
RUN apt-get update && \
    apt-get install -y \
        g++ \
        make \
        cmake \
        unzip \
        libcurl4-openssl-dev

# Copy function code
RUN mkdir -p ${FUNCTION_DIR}
COPY . ${FUNCTION_DIR}

WORKDIR ${FUNCTION_DIR}

# Install Node.js dependencies
RUN npm install

# Install the runtime interface client
RUN npm install aws-lambda-ric

# Grab a fresh slim copy of the image to reduce the final size
FROM node:20-bookworm-slim

# Required for Node runtimes which use npm@8.6.0+ because
```

```
# by default npm writes logs under /home/.npm and Lambda fs is read-only
ENV NPM_CONFIG_CACHE=/tmp/.npm

# Include global arg in this stage of the build
ARG FUNCTION_DIR

# Set working directory to function root directory
WORKDIR ${FUNCTION_DIR}

# Copy in the built dependencies
COPY --from=build-image ${FUNCTION_DIR} ${FUNCTION_DIR}

# Set runtime interface client as default command for the container runtime
ENTRYPOINT ["/usr/local/bin/npx", "aws-lambda-ric"]
# Pass the name of the function handler as an argument to the runtime
CMD ["index.handler"]
```

5. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test the image. You can [build the emulator into your image](#) or use the following procedure to install it on your local machine.

To install and run the runtime interface emulator on your local machine

1. From your project directory, run the following command to download the runtime interface emulator (x86-64 architecture) from GitHub and install it on your local machine.

Linux/macOS

```
mkdir -p ~/.aws-lambda-rie && \
  curl -Lo ~/.aws-lambda-rie/aws-lambda-rie https://github.com/aws/aws-lambda-
runtime-interface-emulator/releases/latest/download/aws-lambda-rie && \
  chmod +x ~/.aws-lambda-rie/aws-lambda-rie
```

To install the arm64 emulator, replace the GitHub repository URL in the previous command with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/
download/aws-lambda-rie-arm64
```

PowerShell

```
$dirPath = "$HOME\.aws-lambda-rie"
if (-not (Test-Path $dirPath)) {
    New-Item -Path $dirPath -ItemType Directory
}

$downloadLink = "https://github.com/aws/aws-lambda-runtime-interface-emulator/
releases/latest/download/aws-lambda-rie"
$destinationPath = "$HOME\.aws-lambda-rie\aws-lambda-rie"
Invoke-WebRequest -Uri $downloadLink -OutFile $destinationPath
```

To install the arm64 emulator, replace the `$downloadLink` with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/
download/aws-lambda-rie-arm64
```

2. Start the Docker image with the **docker run** command. Note the following:
 - `docker-image` is the image name and `test` is the tag.
 - `/usr/local/bin/npx aws-lambda-ric index.handler` is the ENTRYPOINT followed by the CMD from your Dockerfile.

Linux/macOS

```
docker run --platform linux/amd64 -d -v ~/.aws-lambda-rie:/aws-lambda -p
9000:8080 \
  --entrypoint /aws-lambda/aws-lambda-rie \
  docker-image:test \
  /usr/local/bin/npx aws-lambda-ric index.handler
```

PowerShell

```
docker run --platform linux/amd64 -d -v "$HOME\.aws-lambda-rie:/aws-lambda" -p
9000:8080 `
--entrypoint /aws-lambda/aws-lambda-rie `
docker-image:test `
/usr/local/bin/npx aws-lambda-ric index.handler
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

3. Post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following Invoke-WebRequest command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{} ' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType  
"application/json"
```

4. Get the container ID.

```
docker ps
```

5. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

 **Note**

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:

- `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
- Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Working with layers for Node.js Lambda functions

Use [Lambda layers](#) to package code and dependencies that you want to reuse across multiple functions. Layers usually contain library dependencies, a [custom runtime](#), or configuration files. Creating a layer involves three general steps:

1. Package your layer content. This means creating a .zip file archive that contains the dependencies you want to use in your functions.
2. Create the layer in Lambda.
3. Add the layer to your functions.

Topics

- [Package your layer content](#)
- [Create the layer in Lambda](#)
- [Add the layer to your function](#)
- [Sample app](#)

Package your layer content

To create a layer, bundle your packages into a .zip file archive that meets the following requirements:

- Build the layer using the same Node.js version that you plan to use for the Lambda function. For example, if you build your layer using Node.js 24, use the Node.js 24 runtime for your function.
- Your layer's .zip file must use one of these directory structures:
 - nodejs/node_modules
 - nodejs/node~~X~~/node_modules (where ~~X~~ is your Node.js version, for example node22)

For more information, see [Layer paths for each Lambda runtime](#).

- The packages in your layer must be compatible with Linux. Lambda functions run on Amazon Linux.

You can create layers that contain either third-party Node.js libraries installed with npm (such as `axios` or `lodash`) or your own JavaScript modules.

Third-party dependencies

To create a layer using npm packages

1. Create the required directory structure and install packages directly into it:

```
mkdir -p nodejs
npm install --prefix nodejs lodash axios
```

This command installs the packages directly into the `nodejs/node_modules` directory, which is the structure that Lambda requires.

Note

For packages with native dependencies or binary components (such as [sharp](#) or [bcrypt](#)), ensure that they're compatible with the Lambda Linux environment and your function's [architecture](#). You might need to use the `--platform` flag:

```
npm install --prefix nodejs --platform=linux --arch=x64 sharp
```

For more complex native dependencies, you might need to compile them in a Linux environment that matches the Lambda runtime. You can use Docker for this purpose.

2. Zip the layer content:

Linux/macOS

```
zip -r layer.zip nodejs/
```

PowerShell

```
Compress-Archive -Path .\nodejs -DestinationPath .\layer.zip
```

The directory structure of your `.zip` file should look like this:

```
nodejs/
### package.json
### package-lock.json
```

```
### node_modules/  
### lodash/  
### axios/  
### (dependencies of the other packages)
```

Note

- Make sure your .zip file includes the nodejs directory at the root level with node_modules inside it. This structure ensures that Lambda can locate and import your packages.
- The package.json and package-lock.json files in the nodejs/ directory are used by npm for dependency management but are not required by Lambda for layer functionality. Each installed package already contains its own package.json file that defines how Lambda imports the package.

Custom JavaScript modules

To create a layer using your own code

1. Create the required directory structure for your layer:

```
mkdir -p nodejs/node_modules/validator  
cd nodejs/node_modules/validator
```

2. Create a package.json file for your custom module to define how it should be imported:

Example nodejs/node_modules/validator/package.json

```
{  
  "name": "validator",  
  "version": "1.0.0",  
  "type": "module",  
  "main": "index.mjs"  
}
```

3. Create your JavaScript module file:

Example nodejs/node_modules/validator/index.mjs

```
export function validateOrder(orderData) {
  // Validates an order and returns formatted data
  const requiredFields = ['productId', 'quantity'];

  // Check required fields
  const missingFields = requiredFields.filter(field => !(field in orderData));
  if (missingFields.length > 0) {
    throw new Error(`Missing required fields: ${missingFields.join(', ')}`);
  }

  // Validate quantity
  const quantity = orderData.quantity;
  if (!Number.isInteger(quantity) || quantity < 1) {
    throw new Error('Quantity must be a positive integer');
  }

  // Format and return the validated data
  return {
    productId: String(orderData.productId),
    quantity: quantity,
    shippingPriority: orderData.priority || 'standard'
  };
}

export function formatResponse(statusCode, body) {
  // Formats the API response
  return {
    statusCode: statusCode,
    body: JSON.stringify(body)
  };
}
```

4. Zip the layer content:

Linux/macOS

```
zip -r layer.zip nodejs/
```

PowerShell

```
Compress-Archive -Path .\nodejs -DestinationPath .\layer.zip
```

The directory structure of your .zip file should look like this:

```
nodejs/  
### node_modules/  
    ### validator/  
        ### package.json  
        ### index.mjs
```

5. In your function, import and use the modules. Example:

```
import { validateOrder, formatResponse } from 'validator';  
  
export const handler = async (event) => {  
  try {  
    // Parse the order data from the event body  
    const orderData = JSON.parse(event.body || '{}');  
  
    // Validate and format the order  
    const validatedOrder = validateOrder(orderData);  
  
    return formatResponse(200, {  
      message: 'Order validated successfully',  
      order: validatedOrder  
    });  
  } catch (error) {  
    if (error instanceof Error && error.message.includes('Missing required  
fields')) {  
      return formatResponse(400, {  
        error: error.message  
      });  
    }  
  
    return formatResponse(500, {  
      error: 'Internal server error'  
    });  
  }  
}
```

```
};
```

You can use the following [test event](#) to invoke the function:

```
{
  "body": "{\"productId\": \"ABC123\", \"quantity\": 2, \"priority\": \"express\"}"
}
```

Expected response:

```
{
  "statusCode": 200,
  "body": "{\"message\": \"Order validated successfully\", \"order\": {\"productId\": \"ABC123\", \"quantity\": 2, \"shippingPriority\": \"express\"}}"
```

Create the layer in Lambda

You can publish your layer using either the AWS CLI or the Lambda console.

AWS CLI

Run the [publish-layer-version](#) AWS CLI command to create the Lambda layer:

```
aws lambda publish-layer-version --layer-name my-layer --zip-file fileb://layer.zip
--compatible-runtimes nodejs24.x
```

The [compatible runtimes](#) parameter is optional. When specified, Lambda uses this parameter to filter layers in the Lambda console.

Console

To create a layer (console)

1. Open the [Layers page](#) of the Lambda console.
2. Choose **Create layer**.
3. Choose **Upload a .zip file**, and then upload the .zip archive that you created earlier.

4. (Optional) For **Compatible runtimes**, choose the Node.js runtime that corresponds to the Node.js version you used to build your layer.
5. Choose **Create**.

Add the layer to your function

AWS CLI

To attach the layer to your function, run the [update-function-configuration](#) AWS CLI command. For the `--layers` parameter, use the layer ARN. The ARN must specify the version (for example, `arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1`). For more information, see [Layers and layer versions](#).

```
aws lambda update-function-configuration --function-name my-function --cli-binary-format raw-in-base64-out --layers "arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1"
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

Console

To add a layer to a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function.
3. Scroll down to the **Layers** section, and then choose **Add a layer**.
4. Under **Choose a layer**, select **Custom layers**, and then choose your layer.

Note

If you didn't add a [compatible runtime](#) when you created the layer, your layer won't be listed here. You can specify the layer ARN instead.

5. Choose **Add**.

Sample app

For more examples of how to use Lambda layers, see the [layer-nodejs](#) sample application in the AWS Lambda Developer Guide GitHub repository. This application includes a layer that contains the [lodash](#) library. After creating the layer, you can deploy and invoke the corresponding function to confirm that the layer works as expected.

Using the Lambda context object to retrieve Node.js function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides methods and properties that provide information about the invocation, function, and execution environment.

Context methods

- `getRemainingTimeInMillis()` – Returns the number of milliseconds left before the execution times out.

Context properties

- `functionName` – The name of the Lambda function.
- `functionVersion` – The [version](#) of the function.
- `invokedFunctionArn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `memoryLimitInMB` – The amount of memory that's allocated for the function.
- `awsRequestId` – The identifier of the invocation request.
- `logGroupName` – The log group for the function.
- `logStreamName` – The log stream for the function instance.
- `identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
 - `cognitoIdentityId` – The authenticated Amazon Cognito identity.
 - `cognitoIdentityPoolId` – The Amazon Cognito identity pool that authorized the invocation.
- `clientContext` – (mobile apps) Client context that's provided to Lambda by the client application.
 - `client.installation_id`
 - `client.app_title`
 - `client.app_version_name`
 - `client.app_version_code`

- `client.app_package_name`
- `env.platform_version`
- `env.platform`
- `env.make`
- `env.model`
- `env.locale`
- `custom` – Custom values that are set by the client application.
- `callbackWaitsForEmptyEventLoop` – By default (`true`), when using a callback-based function handler, Lambda waits for the event loop to be empty after the callback runs before ending the function invoke. Set to `false` to send the response and end the invoke immediately after the callback runs instead of waiting for the event loop to be empty. Outstanding events continue to run during the next invocation. Note that Lambda supports callback-based function handlers for Node.js 22 and earlier runtimes only.

The following example function logs context information and returns the location of the logs.

Example `index.js` file

```
exports.handler = async function(event, context) {
  console.log('Remaining time: ', context.getRemainingTimeInMillis())
  console.log('Function name: ', context.functionName)
  return context.logStreamName
}
```

Log and monitor Node.js Lambda functions

AWS Lambda automatically monitors Lambda functions on your behalf and sends logs to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation to the log stream, and relays logs and other output from your function's code. For more information, see [Sending Lambda function logs to CloudWatch Logs](#).

This page describes how to produce log output from your Lambda function's code, and access logs using the AWS Command Line Interface, the Lambda console, or the CloudWatch console.

Sections

- [Creating a function that returns logs](#)
- [Using Lambda advanced logging controls with Node.js](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)
- [Viewing logs using the AWS Command Line Interface \(AWS CLI\)](#)
- [Deleting logs](#)

Creating a function that returns logs

To output logs from your function code, you can use methods on the [console object](#), or any logging library that writes to `stdout` or `stderr`. The following example logs the values of environment variables and the event object.

Note

We recommend that you use techniques such as input validation and output encoding when logging inputs. If you log input data directly, an attacker might be able to use your code to make tampering hard to detect, forge log entries, or bypass log monitors. For more information, see [Improper Output Neutralization for Logs](#) in the *Common Weakness Enumeration*.

Example index.js file – Logging

```
exports.handler = async function(event, context) {
```

```

console.log("ENVIRONMENT VARIABLES\n" + JSON.stringify(process.env, null, 2))
console.info("EVENT\n" + JSON.stringify(event, null, 2))
console.warn("Event not processed.")
return context.logStreamName
}

```

Example log format

```

```

The Node.js runtime logs the START, END, and REPORT lines for each invocation. It adds a timestamp, request ID, and log level to each entry logged by the function. The report line provides the following details.

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.

- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

You can view logs in the Lambda console, in the CloudWatch Logs console, or from the command line.

Using Lambda advanced logging controls with Node.js

To give you more control over how your functions' logs are captured, processed, and consumed, you can configure the following logging options for supported Node.js runtimes:

- **Log format** - select between plain text and structured JSON format for your function's logs
- **Log level** - for logs in JSON format, choose the detail level of the logs Lambda sends to Amazon CloudWatch, such as ERROR, DEBUG, or INFO
- **Log group** - choose the CloudWatch log group your function sends logs to

For more information about these logging options, and instructions on how to configure your function to use them, see [the section called “Configuring advanced logging controls for Lambda functions”](#).

To use the log format and log level options with your Node.js Lambda functions, see the guidance in the following sections.

Using structured JSON logs with Node.js

If you select JSON for your function's log format, Lambda will send logs output using the console methods of `console.trace`, `console.debug`, `console.log`, `console.info`, `console.error`, and `console.warn` to CloudWatch as structured JSON. Each JSON log object contains at least four key value pairs with the following keys:

- "timestamp" - the time the log message was generated
- "level" - the log level assigned to the message
- "message" - the contents of the log message
- "requestId" - the unique request ID for the function invocation

Depending on the logging method that your function uses, this JSON object may also contain additional key pairs. For example, if your function uses `console` methods to log error objects using multiple arguments, the JSON object will contain extra key value pairs with the keys `errorMessage`, `errorType`, and `stackTrace`.

If your code already uses another logging library, such as Powertools for AWS Lambda, to produce JSON structured logs, you don't need to make any changes. Lambda doesn't double-encode any logs that are already JSON encoded, so your function's application logs will continue to be captured as before.

For more information about using the Powertools for AWS Lambda logging package to create JSON structured logs in the Node.js runtime, see [the section called "Logging"](#).

Example JSON formatted log outputs

The following examples shows how various log outputs generated using the `console` methods with single and multiple arguments are captured in CloudWatch Logs when you set your function's log format to JSON.

The first example uses the `console.error` method to output a simple string.

Example Node.js logging code

```
export const handler = async (event) => {
  console.error("This is a warning message");
  ...
}
```

Example JSON log record

```
{
  "timestamp": "2025-11-01T00:21:51.358Z",
  "level": "ERROR",
  "message": "This is a warning message",
  "requestId": "93f25699-2cbf-4976-8f94-336a0aa98c6f"
```

```
}
```

You can also output more complex structured log messages using either single or multiple arguments with the `console` methods. In the next example, you use `console.log` to output two key value pairs using a single argument. Note that the "message" field in the JSON object Lambda sends to CloudWatch Logs is not stringified.

Example Node.js logging code

```
export const handler = async (event) => {  
  console.log({data: 12.3, flag: false});  
  ...  
}
```

Example JSON log record

```
{  
  "timestamp": "2025-12-08T23:21:04.664Z",  
  "level": "INFO",  
  "requestId": "405a4537-9226-4216-ac59-64381ec8654a",  
  "message": {  
    "data": 12.3,  
    "flag": false  
  }  
}
```

In the next example, you again use the `console.log` method to create a log output. This time, the method takes two arguments, a map containing two key value pairs and an identifying string. Note that in this case, because you have supplied two arguments, Lambda stringifies the "message" field.

Example Node.js logging code

```
export const handler = async (event) => {  
  console.log('Some object - ', {data: 12.3, flag: false});  
  ...  
}
```

Example JSON log record

```
{
```

```

    "timestamp": "2025-12-08T23:21:04.664Z",
    "level": "INFO",
    "requestId": "405a4537-9226-4216-ac59-64381ec8654a",
    "message": "Some object -  { data: 12.3, flag: false }"
  }

```

Lambda assigns outputs generated using `console.log` the log level `INFO`.

The final example shows how error objects can be output to CloudWatch Logs using the `console` methods. Note that when you log error objects using multiple arguments, Lambda adds the fields `errorMessage`, `errorType`, and `stackTrace` to the log output.

Example Node.js logging code

```

export const handler = async (event) => {
  let e1 = new ReferenceError("some reference error");
  let e2 = new SyntaxError("some syntax error");
  console.log(e1);
  console.log("errors logged - ", e1, e2);
};

```

Example JSON log record

```

{
  "timestamp": "2025-12-08T23:21:04.632Z",
  "level": "INFO",
  "requestId": "405a4537-9226-4216-ac59-64381ec8654a",
  "message": {
    "errorType": "ReferenceError",
    "errorMessage": "some reference error",
    "stackTrace": [
      "ReferenceError: some reference error",
      "    at Runtime.handler (file:///var/task/index.mjs:3:12)",
      "    at Runtime.handleOnceNonStreaming (file:///var/runtime/index.mjs:1173:29)"
    ]
  }
}

{
  "timestamp": "2025-12-08T23:21:04.646Z",
  "level": "INFO",

```

```

    "requestId": "405a4537-9226-4216-ac59-64381ec8654a",
    "message": "errors logged - ReferenceError: some reference error
\n    at Runtime.handler (file:///var/task/index.mjs:3:12)\n    at
Runtime.handleOnceNonStreaming
    (file:///var/runtime/index.mjs:1173:29) SyntaxError: some syntax
error\n    at Runtime.handler (file:///var/task/index.mjs:4:12)\n    at
Runtime.handleOnceNonStreaming
    (file:///var/runtime/index.mjs:1173:29)",
    "errorType": "ReferenceError",
    "errorMessage": "some reference error",
    "stackTrace": [
        "ReferenceError: some reference error",
        "    at Runtime.handler (file:///var/task/index.mjs:3:12)",
        "    at Runtime.handleOnceNonStreaming (file:///var/runtime/index.mjs:1173:29)"
    ]
}

```

When logging multiple error types, the extra fields `errorMessage`, `errorType`, and `stackTrace` are extracted from the first error type supplied to the `console` method.

Using embedded metric format (EMF) client libraries with structured JSON logs

AWS provides open-sourced client libraries for Node.js which you can use to create [embedded metric format](#) (EMF) logs. If you have existing functions that use these libraries and you change your function's log format to JSON, CloudWatch may no longer recognize the metrics emitted by your code.

If your code currently emits EMF logs directly using `console.log` or by using Powertools for AWS Lambda (TypeScript), CloudWatch will also be unable to parse these if you change your function's log format to JSON.

Important

To ensure that your functions' EMF logs continue to be properly parsed by CloudWatch, update your [EMF](#) and [Powertools for AWS Lambda](#) libraries to the latest versions. If switching to the JSON log format, we also recommend that you carry out testing to ensure compatibility with your function's embedded metrics. If your code emits EMF logs directly using `console.log`, change your code to output those metrics directly to `stdout` as shown in the following code example.

Example code emitting embedded metrics to stdout

```
process.stdout.write(JSON.stringify(
  {
    "_aws": {
      "Timestamp": Date.now(),
      "CloudWatchMetrics": [{
        "Namespace": "lambda-function-metrics",
        "Dimensions": [["functionVersion"]],
        "Metrics": [{
          "Name": "time",
          "Unit": "Milliseconds",
          "StorageResolution": 60
        }]
      }]
    },
    "functionVersion": "$LATEST",
    "time": 100,
    "requestId": context.awsRequestId
  }
) + "\n")
```

Using log-level filtering with Node.js

For AWS Lambda to filter your application logs according to their log level, your function must use JSON formatted logs. You can achieve this in two ways:

- Create log outputs using the standard console methods and configure your function to use JSON log formatting. AWS Lambda then filters your log outputs using the “level” key value pair in the JSON object described in [the section called “Using structured JSON logs with Node.js”](#). To learn how to configure your function’s log format, see [the section called “Configuring advanced logging controls for Lambda functions”](#).
- Use another logging library or method to create JSON structured logs in your code that include a “level” key value pair defining the level of the log output. For example, you can use Powertools for AWS Lambda to generate JSON structured log outputs from your code. See [the section called “Logging”](#) to learn more about using Powertools with the Node.js runtime.

For Lambda to filter your function's logs, you must also include a "timestamp" key value pair in your JSON log output. The time must be specified in valid [RFC 3339](#) timestamp format. If you

don't supply a valid timestamp, Lambda will assign the log the level INFO and add a timestamp for you.

When you configure your function to use log-level filtering, you select the level of logs you want AWS Lambda to send to CloudWatch Logs from the following options:

Log level	Standard usage
TRACE (most detail)	The most fine-grained information used to trace the path of your code's execution
DEBUG	Detailed information for system debugging
INFO	Messages that record the normal operation of your function
WARN	Messages about potential errors that may lead to unexpected behavior if unaddressed
ERROR	Messages about problems that prevent the code from performing as expected
FATAL (least detail)	Messages about serious errors that cause the application to stop functioning

Lambda sends logs of the selected level and lower to CloudWatch. For example, if you configure a log level of WARN, Lambda will send logs corresponding to the WARN, ERROR, and FATAL levels.

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElk0iA4N2QwNDRiOC1mMTU0LTExZTgtOGNkYS0yOTc0YzVlNGZiMjEgVmVyc2l1vb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB
```

The `base64` utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"//g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "statusCode": 200,
  "executedVersion": "$LATEST"
}
{
  "events": [
    {
      "timestamp": 1559763003171,
      "message": "START RequestId: 4ce9340a-b765-490f-ad8a-02ab3415e2bf Version: $LATEST\n",

}

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Instrumenting Node.js code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of two SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for Node.js](#) – An SDK for generating and sending trace data to X-Ray.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

Sections

- [Using ADOT to instrument your Node.js functions](#)
- [Using the X-Ray SDK to instrument your Node.js functions](#)
- [Activating tracing with the Lambda console](#)
- [Activating tracing with the Lambda API](#)
- [Activating tracing with CloudFormation](#)
- [Interpreting an X-Ray trace](#)
- [Storing runtime dependencies in a layer \(X-Ray SDK\)](#)

Using ADOT to instrument your Node.js functions

ADOT provides fully managed Lambda [layers](#) that package everything you need to collect telemetry data using the OTel SDK. By consuming this layer, you can instrument your Lambda functions without having to modify any function code. You can also configure your layer to do custom initialization of OTel. For more information, see [Custom configuration for the ADOT Collector on Lambda](#) in the ADOT documentation.

For Node.js runtimes, you can add the **AWS managed Lambda layer for ADOT Javascript** to automatically instrument your functions. For detailed instructions on how to add this layer, see [AWS Distro for OpenTelemetry Lambda Support for JavaScript](#) in the ADOT documentation.

Using the X-Ray SDK to instrument your Node.js functions

To record details about calls that your Lambda function makes to other resources in your application, you can also use the AWS X-Ray SDK for Node.js. To get the SDK, add the `aws-xray-sdk-core` package to your application's dependencies.

Example [blank-nodejs/package.json](#)

```
{
  "name": "blank-nodejs",
  "version": "1.0.0",
  "private": true,
  "devDependencies": {
    "jest": "29.7.0"
  },
  "dependencies": {
    "@aws-sdk/client-lambda": "3.345.0",
    "aws-xray-sdk-core": "3.5.3"
  },
  "scripts": {
    "test": "jest"
  }
}
```

To instrument AWS SDK clients in the [AWS SDK for JavaScript v3](#), wrap the client instance with the `captureAWSSv3Client` method.

Example [blank-nodejs/function/index.js](#) – Tracing an AWS SDK client

```
const AWSXRay = require('aws-xray-sdk-core');
const { LambdaClient, GetAccountSettingsCommand } = require('@aws-sdk/client-lambda');

// Create client outside of handler to reuse
const lambda = AWSXRay.captureAWSv3Client(new LambdaClient());

// Handler
exports.handler = async function(event, context) {
  event.Records.forEach(record => {
    ...
```

The Lambda runtime sets some environment variables to configure the X-Ray SDK. For example, Lambda sets `AWS_XRAY_CONTEXT_MISSING` to `LOG_ERROR` to avoid throwing runtime errors from the X-Ray SDK. To set a custom context missing strategy, override the environment variable in your function configuration to have no value, and then you can set the context missing strategy programmatically.

Example initialization code

```
const AWSXRay = require('aws-xray-sdk-core');

// Configure the context missing strategy to do nothing
AWSXRay.setContextMissingStrategy(() => {});
```

For more information, see [the section called “Environment variables”](#).

After you add the correct dependencies and make the necessary code changes, activate tracing in your function's configuration via the Lambda console or the API.

Activating tracing with the Lambda console

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Monitoring and operations tools**.

4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.
6. Choose **Save**.

Activating tracing with the Lambda API

Configure tracing on your Lambda function with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Activating tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in a CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Lambda::Function
    Properties:
      TracingConfig:
        Mode: Active
      ...
```

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

Example [template.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      Tracing: Active
      ...
```

Interpreting an X-Ray trace

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

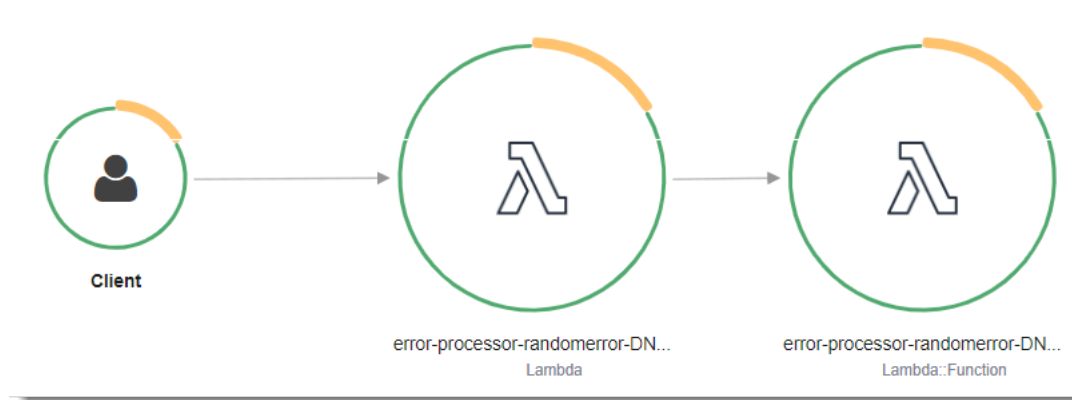

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

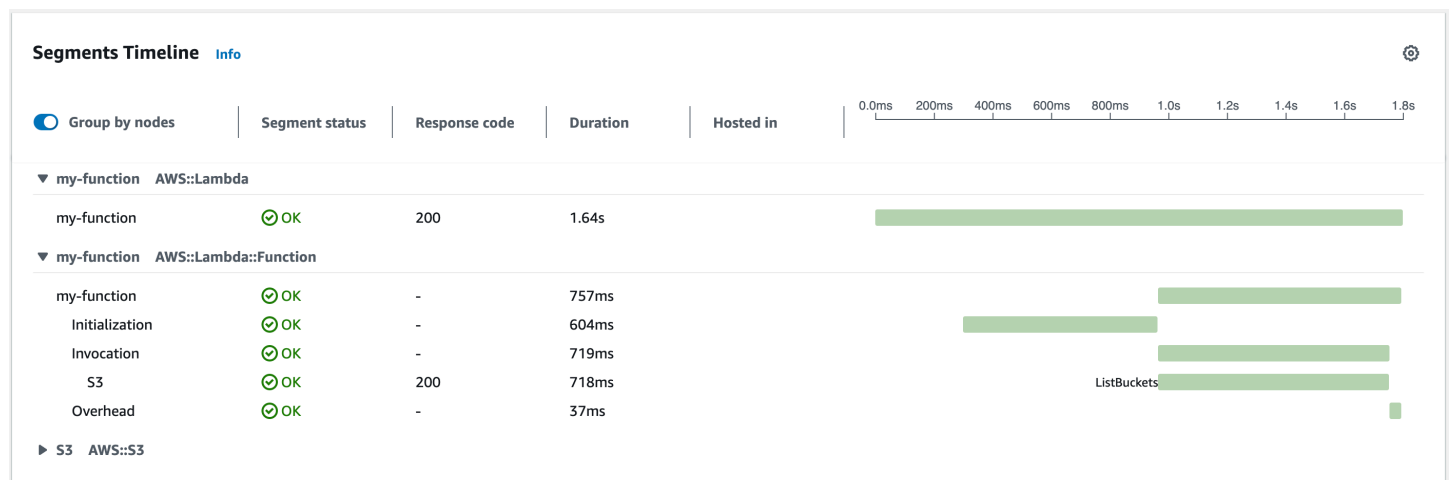

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling

rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an Invocation subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called “Understanding X-Ray traces”](#).

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see the [AWS X-Ray SDK for Node.js](#) in the *AWS X-Ray Developer Guide*.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

Storing runtime dependencies in a layer (X-Ray SDK)

If you use the X-Ray SDK to instrument AWS SDK clients your function code, your deployment package can become quite large. To avoid uploading runtime dependencies every time you update your function code, package the X-Ray SDK in a [Lambda layer](#).

The following example shows an `AWS::Serverless::LayerVersion` resource that stores the AWS X-Ray SDK for Node.js.

Example [template.yml](#) – Dependencies layer

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: function/.
      Tracing: Active
      Layers:
        - !Ref libs
        ...
  libs:
    Type: AWS::Serverless::LayerVersion
    Properties:
      LayerName: blank-nodejs-lib
      Description: Dependencies for the blank sample app.
      ContentUri: lib/.
      CompatibleRuntimes:
        - nodejs24.x
```

With this configuration, you update the library layer only if you change your runtime dependencies. Since the function deployment package contains only your code, this can help reduce upload times.

Creating a layer for dependencies requires build changes to generate the layer archive prior to deployment. For a working example, see the [blank-nodejs](#) sample application.

Building Lambda functions with TypeScript

You can use the Node.js runtime to run TypeScript code in AWS Lambda. Because Node.js doesn't run TypeScript code natively, you must first transpile your TypeScript code into JavaScript. Then, use the JavaScript files to deploy your function code to Lambda. Your code runs in an environment that includes the AWS SDK for JavaScript, with credentials from an AWS Identity and Access Management (IAM) role that you manage. To learn more about the SDK versions included with the Node.js runtimes, see [the section called “Runtime-included SDK versions”](#).

Lambda supports the following Node.js runtimes.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
Node.js 24	nodejs24.x	Amazon Linux 2023	Apr 30, 2028	Jun 1, 2028	Jul 1, 2028
Node.js 22	nodejs22.x	Amazon Linux 2023	Apr 30, 2027	Jun 1, 2027	Jul 1, 2027
Node.js 20	nodejs20.x	Amazon Linux 2023	Apr 30, 2026	Aug 31, 2026	Sep 30, 2026

Setting up a TypeScript development environment

Use a local integrated development environment (IDE) or text editor to write your TypeScript function code. You can't create TypeScript code on the Lambda console.

You can use either [esbuild](#) or Microsoft's TypeScript compiler (tsc) to transpile your TypeScript code into JavaScript. The [AWS Serverless Application Model \(AWS SAM\)](#) and the [AWS Cloud Development Kit \(AWS CDK\)](#) both use esbuild.

When using esbuild, consider the following:

- There are several [TypeScript caveats](#).
- You must configure your TypeScript transpilation settings to match the Node.js runtime that you plan to use. For more information, see [Target](#) in the esbuild documentation. For an example of a **tsconfig.json** file that demonstrates how to target a specific Node.js version supported by Lambda, refer to the [TypeScript GitHub repository](#).
- esbuild doesn't perform type checks. To check types, use the tsc compiler. Run `tsc -noEmit` or add a "noEmit" parameter to your **tsconfig.json** file, as shown in the following example. This configures tsc to not emit JavaScript files. After checking types, use esbuild to convert the TypeScript files into JavaScript.

Example tsconfig.json

```
{
  "compilerOptions": {
    "target": "es2020",
    "strict": true,
    "preserveConstEnums": true,
    "noEmit": true,
    "sourceMap": false,
    "module": "commonjs",
    "moduleResolution": "node",
    "esModuleInterop": true,
    "skipLibCheck": true,
    "forceConsistentCasingInFileNames": true,
    "isolatedModules": true,
  },
  "exclude": ["node_modules", "**/*.test.ts"]
}
```

Type definitions for Lambda

The [@types/aws-lambda](#) package provides type definitions for Lambda functions. Install this package when your function uses any of the following:

- Common AWS event sources, such as:
 - APIGatewayProxyEvent: For [Amazon API Gateway proxy integrations](#)
 - SNSEvent: For [Amazon Simple Notification Service notifications](#)
 - SQSEvent: For [Amazon Simple Queue Service messages](#)
 - S3Event: For [S3 trigger events](#)
 - DynamoDBStreamEvent: For [Amazon DynamoDB Streams](#)
- The Lambda [Context](#) object
- The [callback](#) handler pattern

To add the Lambda type definitions to your function, install `@types/aws-lambda` as a development dependency:

```
npm install -D @types/aws-lambda
```

Then, import the types from `aws-lambda`:

```
import { Context, S3Event, APIGatewayProxyEvent } from 'aws-lambda';

export const handler = async (event: S3Event, context: Context) => {
  // Function code
};
```

The `import ... from 'aws-lambda'` statement imports the type definitions. It does not import the `aws-lambda` npm package, which is an unrelated third-party tool. For more information, see [aws-lambda](#) in the DefinitelyTyped GitHub repository.

Note

You don't need [@types/aws-lambda](#) when using your own custom type definitions. For an example function that defines its own type for an event object, see [Example TypeScript Lambda function code](#).

Define Lambda function handler in TypeScript

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in TypeScript, including options for project setup, naming conventions, and best practices. This page also includes an example of a TypeScript Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (Amazon S3) bucket. For information about how to deploy your function after writing it, see [the section called “Deploy .zip file archives”](#) or [the section called “Deploy container images”](#).

Setting up your TypeScript project

Use a local integrated development environment (IDE) or text editor to write your TypeScript function code. You can't create TypeScript code on the Lambda console.

There are multiple ways to initialize a TypeScript Lambda project. For example, you can create a project using npm, create an [AWS SAM application](#), or create an [AWS CDK application](#). To create the project using npm:

```
npm init
```

Your function code lives in a `.ts` file, which you transpile into a JavaScript file at build time. You can use either [esbuild](#) or Microsoft's TypeScript compiler (`tsc`) to transpile your TypeScript code into JavaScript. To use esbuild, add it as a development dependency:

```
npm install -D esbuild
```

A typical TypeScript Lambda function project follows this general structure:

```
/project-root
  ### index.ts - Contains main handler
  ### dist/ - Contains compiled JavaScript
  ### package.json - Project metadata and dependencies
  ### package-lock.json - Dependency lock file
  ### tsconfig.json - TypeScript configuration
  ### node_modules/ - Installed dependencies
```

Example TypeScript Lambda function code

The following example Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket. This example defines a custom event type (`OrderEvent`). To learn how to import type definitions for AWS event sources, see [Type definitions for Lambda](#).

Note

This example uses an ES module handler. Lambda supports both ES module and CommonJS handlers. For more information, see [CommonJS and ES Modules](#).

Example `index.ts` Lambda function

```
import { S3Client, PutObjectCommand } from '@aws-sdk/client-s3';

// Initialize the S3 client outside the handler for reuse
const s3Client = new S3Client();

// Define the shape of the input event
type OrderEvent = {
```

```

    order_id: string;
    amount: number;
    item: string;
}

/**
 * Lambda handler for processing orders and storing receipts in S3.
 */
export const handler = async (event: OrderEvent): Promise<string> => {
    try {
        // Access environment variables
        const bucketName = process.env.RECEIPT_BUCKET;
        if (!bucketName) {
            throw new Error('RECEIPT_BUCKET environment variable is not set');
        }

        // Create the receipt content and key destination
        const receiptContent = `OrderID: ${event.order_id}\nAmount: $
${event.amount.toFixed(2)}\nItem: ${event.item}`;
        const key = `receipts/${event.order_id}.txt`;

        // Upload the receipt to S3
        await uploadReceiptToS3(bucketName, key, receiptContent);

        console.log(`Successfully processed order ${event.order_id} and stored receipt
in S3 bucket ${bucketName}`);
        return 'Success';
    } catch (error) {
        console.error(`Failed to process order: ${error instanceof Error ?
error.message : 'Unknown error'}`);
        throw error;
    }
};

/**
 * Helper function to upload receipt to S3
 */
async function uploadReceiptToS3(bucketName: string, key: string, receiptContent:
string): Promise<void> {
    try {
        const command = new PutObjectCommand({
            Bucket: bucketName,
            Key: key,
            Body: receiptContent

```

```
});

    await s3Client.send(command);
  } catch (error) {
    throw new Error(`Failed to upload receipt to S3: ${error instanceof Error ?
error.message : 'Unknown error'}`);
  }
}
```

This `index.ts` file contains the following sections of code:

- `import` block: Use this block to include libraries that your Lambda function requires, such as [AWS SDK clients](#).
- `const s3Client` declaration: This initializes an [Amazon S3 client](#) outside of the handler function. This causes Lambda to run this code during the [initialization phase](#), and the client is preserved for [reuse across multiple invocations](#).
- `type OrderEvent`: Defines the structure of the expected input event.
- `export const handler`: This is the main handler function that Lambda invokes. When deploying your function, specify `index.handler` for the [Handler](#) property. The value of the Handler property is the file name and the name of the exported handler method, separated by a dot.
- `uploadReceiptToS3` function: This is a helper function that's referenced by the main handler function.

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

CommonJS and ES Modules

Node.js supports two module systems: CommonJS and ECMAScript modules (ES modules). Lambda recommends using ES modules as it supports top-level `await`, which enables asynchronous tasks to be completed during [execution environment initialization](#).

Node.js treats files with a `.cjs` file name extension as CommonJS modules while a `.mjs` extension denotes ES modules. By default, Node.js treats files with the `.js` file name extension as CommonJS modules. You can configure Node.js to treat `.js` files as ES modules by specifying the type as `module` in the function's `package.json` file. You can configure Node.js in Lambda

to detect automatically whether a `.js` file should be treated as CommonJS or as an ES module by adding the `--experimental-detect-module` flag to the `NODE_OPTIONS` environment variable. For more information, see [Experimental Node.js features](#).

The following examples show function handlers written using both ES modules and CommonJS modules. The remaining examples on this page all use ES modules.

Node.js initialization

Node.js uses a non-blocking I/O model that supports efficient asynchronous operations using an event loop. For example, if Node.js makes a network call, the function continues to process other operations without blocking on a network response. When the network response is received, it is placed into the callback queue. Tasks from the queue are processed when the current task completes.

Lambda recommends using top-level `await` so that asynchronous tasks initiated during execution environment initialization are completed during initialization. Asynchronous tasks that are not completed during initialization will typically run during the first function invoke. This can cause unexpected behavior or errors. For example, your function initialization may make a network call to fetch a parameter from AWS Parameter Store. If this task is not completed during initialization, the value may be null during an invocation. There can also be a delay between initialization and invoke which can trigger errors in time-sensitive operations. In particular, AWS service calls can rely on time-sensitive request signatures, resulting in service call failures if the call is not completed during the initialization phase. Completing tasks during initialization typically improves cold-start performance, and first invoke performance when using Provisioned Concurrency. For more information, see our blog post [Using Node.js ES modules and top-level await in AWS Lambda](#).

Handler naming conventions

When you configure a function, the value of the [Handler](#) setting is the file name and the name of the exported handler method, separated by a dot. The default for functions created in the console and for examples in this guide is `index.handler`. This indicates the `handler` method that's exported from the `index.js` or `index.mjs` file.

If you create a function in the console using a different file name or function handler name, you must edit the default handler name.

To change the function handler name (console)

1. Open the [Functions](#) page of the Lambda console and choose your function.

2. Choose the **Code** tab.
3. Scroll down to the **Runtime settings** pane and choose **Edit**.
4. In **Handler**, enter the new name for your function handler.
5. Choose **Save**.

Defining and accessing the input event object

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "order_id": "12345",
  "amount": 199.99,
  "item": "Wireless Headphones"
}
```

When working with Lambda functions in TypeScript, you can define the shape of the input event using a type or interface. In this example, we define the event structure using a type:

```
type OrderEvent = {
  order_id: string;
  amount: number;
  item: string;
}
```

After you define the type or interface, use it in your handler's signature to ensure type safety:

```
export const handler = async (event: OrderEvent): Promise<string> => {
```

During compilation, TypeScript validates that the event object contains the required fields with the correct types. For example, the TypeScript compiler reports an error if you try to use `event.order_id` as a number or `event.amount` as a string.

Valid handler patterns for TypeScript functions

We recommend that you use [async/await](#) to declare the function handler instead of using [callbacks](#). Async/await is a concise and readable way to write asynchronous code, without the need

for nested callbacks or chaining promises. With `async/await`, you can write code that reads like synchronous code, while still being asynchronous and non-blocking.

The examples in this section use the `S3Event` type. However, you can use any other AWS event types in the [@types/aws-lambda](#) package, or define your own event type. To use types from `@types/aws-lambda`:

1. Add the `@types/aws-lambda` package as a development dependency:

```
npm install -D @types/aws-lambda
```

2. Import the types you need, such as `Context`, `S3Event`, or `Callback`.

async function handlers (recommended)

The `async` keyword marks a function as asynchronous, and the `await` keyword pauses the execution of the function until a `Promise` is resolved. The handler accepts the following arguments:

- `event`: Contains the input data passed to your function.
- `context`: Contains information about the invocation, function, and execution environment. For more information, see [Using the Lambda context object to retrieve TypeScript function information](#).

Here are the valid signatures for the `async/await` pattern:

```
export const handler = async (event: S3Event): Promise<void> => { };
```

```
export const handler = async (event: S3Event, context: Context): Promise<void> => { };
```

Note

When processing arrays of items asynchronously, make sure to use `await` with `Promise.all` to ensure all operations complete. Methods like `forEach` don't wait for async callbacks to complete. For more information, see [Array.prototype.forEach\(\)](#) in the Mozilla documentation.

Synchronous function handlers

Where your function does not perform any asynchronous tasks, you can use a synchronous function handler, using one of the following function signatures:

```
export const handler = (event: S3Event): void => { };
```

```
export const handler = (event: S3Event, context: Context): void => { };
```

Response streaming function handlers

Lambda supports response streaming with Node.js. Response streaming function handlers use the `awslambda.streamifyResponse()` decorator and take 3 parameters: `event`, `responseStream`, and `context`. The function signature is:

```
export const handler = awslambda.streamifyResponse(async (event: APIGatewayProxyEvent,  
    responseStream: NodeJS.WritableStream, context: Context) => { });
```

For more information, see [Response streaming for Lambda functions](#).

Callback-based function handlers

Note

Callback-based function handlers are only supported up to Node.js 22. Starting from Node.js 24, asynchronous tasks should be implemented using async function handlers.

Callback-based function handlers can use the `event`, `context`, and `callback` arguments. The `callback` argument expects an `Error` and a response, which must be JSON-serializable.

Here is the valid signature for the callback handler pattern:

```
export const handler = (event: S3Event, context: Context, callback: Callback<void>):  
    void => { };
```

The function continues to execute until the [event loop](#) is empty or the function times out. The response isn't sent to the invoker until all event loop tasks are finished. If the function times out,

an error is returned instead. You can configure the runtime to send the response immediately by setting [context.callbackWaitsForEmptyEventLoop](#) to false.

Example TypeScript function with callback

The following example uses `APIGatewayProxyCallback`, which is a specialized callback type specific to API Gateway integrations. Most AWS event sources use the generic `Callback` type shown in the signatures above.

```
import { Context, APIGatewayProxyCallback, APIGatewayEvent } from 'aws-lambda';

export const lambdaHandler = (event: APIGatewayEvent, context: Context, callback:
  APIGatewayProxyCallback): void => {
  console.log(`Event: ${JSON.stringify(event, null, 2)}`);
  console.log(`Context: ${JSON.stringify(context, null, 2)}`);
  callback(null, {
    statusCode: 200,
    body: JSON.stringify({
      message: 'hello world',
    }),
  });
};
```

Using the SDK for JavaScript v3 in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the AWS SDK for JavaScript. All supported Lambda Node.js runtimes include the [SDK for JavaScript version 3](#). However, we strongly recommend that you include the AWS SDK clients that you need in your deployment package. This maximizes [backward compatibility](#) during future Lambda runtime updates.

To add SDK dependencies to your function, use the `npm install` command for the specific SDK clients that you need. In the example code, we used the [Amazon S3 client](#). Add this dependency by running the following command in the directory that contains your `package.json` file:

```
npm install @aws-sdk/client-s3
```

In the function code, import the client and commands that you need, as the example function demonstrates:

```
import { S3Client, PutObjectCommand } from '@aws-sdk/client-s3';
```

Then, initialize an [Amazon S3 client](#):

```
const s3Client = new S3Client();
```

In this example, we initialized our Amazon S3 client outside of the main handler function to avoid having to initialize it every time we invoke our function. After you initialize your SDK client, you can then use it to make API calls for that AWS service. The example code calls the Amazon S3 [PutObject](#) API action as follows:

```
const command = new PutObjectCommand({
  Bucket: bucketName,
  Key: key,
  Body: receiptContent
});
```

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using `process.env`. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following lines of code:

```
// Access environment variables
const bucketName = process.env.RECEIPT_BUCKET;
if (!bucketName) {
  throw new Error('RECEIPT_BUCKET environment variable is not set');
}
```

Using global state

Lambda runs your static code during the [initialization phase](#) before invoking your function for the first time. Resources created during initialization stay in memory between invocations, so you can avoid having to create them every time you invoke your function.

In the example code, the S3 client initialization code is outside the handler. The runtime initializes the client before the function handles its first event, and the client remains available for reuse across all invocations.

Code best practices for TypeScript Lambda functions

Follow these guidelines when building Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. For the Node.js and Python runtimes, these include the AWS SDKs. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation.

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Deploy transpiled TypeScript code in Lambda with .zip file archives

Before you can deploy TypeScript code to AWS Lambda, you need to transpile it into JavaScript. This page explains three ways to build and deploy TypeScript code to Lambda with .zip file archives:

- [Using AWS Serverless Application Model \(AWS SAM\)](#)
- [Using the AWS Cloud Development Kit \(AWS CDK\)](#)
- [Using the AWS Command Line Interface \(AWS CLI\) and esbuild](#)

AWS SAM and AWS CDK simplify building and deploying TypeScript functions. The [AWS SAM template specification](#) provides a simple and clean syntax to describe the Lambda functions, APIs, permissions, configurations, and events that make up your serverless application. The [AWS CDK](#) lets you build reliable, scalable, cost-effective applications in the cloud with the considerable expressive power of a programming language. The AWS CDK is intended for moderately to highly experienced AWS users. Both the AWS CDK and the AWS SAM use esbuild to transpile TypeScript code into JavaScript.

Using AWS SAM to deploy TypeScript code to Lambda

Follow the steps below to download, build, and deploy a sample Hello World TypeScript application using the AWS SAM. This application implements a basic API backend. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function is invoked. The function returns a `hello world` message.

Note

AWS SAM uses esbuild to create Node.js Lambda functions from TypeScript code. esbuild support is currently in public preview. During public preview, esbuild support may be subject to backwards incompatible changes.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#)
- Node.js

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World TypeScript template.

```
sam init --app-template hello-world-typescript --name sam-app --package-type Zip --runtime nodejs24.x
```

2. (Optional) The sample application includes configurations for commonly used tools, such as [ESLint](#) for code linting and [Jest](#) for unit testing. To run lint and test commands:

```
cd sam-app/hello-world
npm install
npm run lint
npm run test
```

3. Build the app.

```
cd sam-app
sam build
```

4. Deploy the app.

```
sam deploy --guided
```

5. Follow the on-screen prompts. To accept the default options provided in the interactive experience, respond with Enter.
6. The output shows the endpoint for the REST API. Open the endpoint in a browser to test the function. You should see this response:

```
{"message":"hello world"}
```

7. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Using the AWS CDK to deploy TypeScript code to Lambda

Follow the steps below to build and deploy a sample TypeScript application using the AWS CDK. This application implements a basic API backend. It consists of an API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function is invoked. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [AWS CDK version 2](#)
- Node.js
- Either [Docker](#) or [esbuild](#)

Deploy a sample AWS CDK application

1. Create a project directory for your new application.

```
mkdir hello-world
cd hello-world
```

2. Initialize the app.

```
cdk init app --language typescript
```

3. Add the [@types/aws-lambda](#) package as a development dependency. This package contains the type definitions for Lambda.

```
npm install -D @types/aws-lambda
```

4. Open the **lib** directory. You should see a file called **hello-world-stack.ts**. Create two new files in this directory: **hello-world.function.ts** and **hello-world.ts**.
5. Open **hello-world.function.ts** and add the following code to the file. This is the code for the Lambda function.

Note

The import statement imports the type definitions from [@types/aws-lambda](#). It does not import the `aws-lambda` NPM package, which is an unrelated third-party tool. For more information, see [aws-lambda](#) in the DefinitelyTyped GitHub repository.

```
import { Context, APIGatewayProxyResult, APIGatewayEvent } from 'aws-lambda';

export const handler = async (event: APIGatewayEvent, context: Context):
  Promise<APIGatewayProxyResult> => {
  console.log(`Event: ${JSON.stringify(event, null, 2)}`);
  console.log(`Context: ${JSON.stringify(context, null, 2)}`);
  return {
    statusCode: 200,
    body: JSON.stringify({
      message: 'hello world',
    }),
  };
};
```

6. Open **hello-world.ts** and add the following code to the file. This contains the [NodejsFunction construct](#), which creates the Lambda function, and the [LambdaRestApi construct](#), which creates the REST API.

```
import { Construct } from 'constructs';
import { NodejsFunction } from 'aws-cdk-lib/aws-lambda-nodejs';
import { LambdaRestApi } from 'aws-cdk-lib/aws-apigateway';

export class HelloWorld extends Construct {
  constructor(scope: Construct, id: string) {
    super(scope, id);
    const helloFunction = new NodejsFunction(this, 'function');
    new LambdaRestApi(this, 'apigw', {
      handler: helloFunction,
    });
  }
}
```

The `NodejsFunction` construct assumes the following by default:

- Your function handler is called `handler`.
- The `.ts` file that contains the function code (**hello-world.function.ts**) is in the same directory as the `.ts` file that contains the construct (**hello-world.ts**). The construct uses the construct's ID ("hello-world") and the name of the Lambda handler file ("function") to find the function code. For example, if your function code is in a file called **hello-world.my-function.ts**, the **hello-world.ts** file must reference the function code like this:

```
const helloFunction = new NodejsFunction(this, 'my-function');
```

You can change this behavior and configure other esbuild parameters. For more information, see [Configuring esbuild](#) in the AWS CDK API reference.

7. Open **hello-world-stack.ts**. This is the code that defines your [AWS CDK stack](#). Replace the code with the following:

```
import { Stack, StackProps } from 'aws-cdk-lib';
import { Construct } from 'constructs';
import { HelloWorld } from './hello-world';

export class HelloWorldStack extends Stack {
  constructor(scope: Construct, id: string, props?: StackProps) {
    super(scope, id, props);
    new HelloWorld(this, 'hello-world');
  }
}
```

8. from the `hello-world` directory containing your `cdk.json` file, deploy your application.

```
cdk deploy
```

9. The AWS CDK builds and packages the Lambda function using esbuild, and then deploys the function to the Lambda runtime. The output shows the endpoint for the REST API. Open the endpoint in a browser to test the function. You should see this response:

```
{"message":"hello world"}
```

This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

Using the AWS CLI and esbuild to deploy TypeScript code to Lambda

The following example demonstrates how to transpile and deploy TypeScript code to Lambda using esbuild and the AWS CLI. esbuild produces one JavaScript file with all dependencies. This is the only file that you need to add to the .zip archive.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- Node.js
- An [execution role](#) for the Lambda function
- For Windows users, a zip file utility such as [7zip](#).

Deploy a sample function

1. On your local machine, create a project directory for your new function.
2. Create a new Node.js project with npm or a package manager of your choice.

```
npm init
```

3. Add the [@types/aws-lambda](#) and [esbuild](#) packages as development dependencies. The @types/aws-lambda package contains the type definitions for Lambda.

```
npm install -D @types/aws-lambda esbuild
```

4. Create a new file called **index.ts**. Add the following code to the new file. This is the code for the Lambda function. The function returns a hello world message. The function doesn't create any API Gateway resources.

Note

The `import` statement imports the type definitions from [@types/aws-lambda](#). It does not import the `aws-lambda` NPM package, which is an unrelated third-party tool. For more information, see [aws-lambda](#) in the DefinitelyTyped GitHub repository.

```
import { Context, APIGatewayProxyResult, APIGatewayEvent } from 'aws-lambda';

export const handler = async (event: APIGatewayEvent, context: Context):
Promise<APIGatewayProxyResult> => {
  console.log(`Event: ${JSON.stringify(event, null, 2)}`);
  console.log(`Context: ${JSON.stringify(context, null, 2)}`);
  return {
    statusCode: 200,
    body: JSON.stringify({
      message: 'hello world',
    }),
  };
};
```

5. Add a build script to the **package.json** file. This configures esbuild to automatically create the .zip deployment package. For more information, see [Build scripts](#) in the esbuild documentation.

Linux and MacOS

```
"scripts": {
  "prebuild": "rm -rf dist",
  "build": "esbuild index.ts --bundle --minify --sourcemap --platform=node --
target=es2020 --outfile=dist/index.js",
  "postbuild": "cd dist && zip -r index.zip index.js*"
},
```

Windows

In this example, the "postbuild" command uses the [7zip](#) utility to create your .zip file. Use your own preferred Windows zip utility and modify the command as necessary.

```
"scripts": {
  "prebuild": "del /q dist",
  "build": "esbuild index.ts --bundle --minify --sourcemap --platform=node --
target=es2020 --outfile=dist/index.js",
  "postbuild": "cd dist && 7z a -tzip index.zip index.js*"
},
```

6. Build the package.

```
npm run build
```

7. Create a Lambda function using the .zip deployment package. Replace the highlighted text with the Amazon Resource Name (ARN) of your [execution role](#).

```
aws lambda create-function --function-name hello-world --runtime "nodejs24.x" --  
role arn:aws:iam::123456789012:role/lambda-ex --zip-file "fileb://dist/index.zip"  
--handler index.handler
```

8. [Run a test event](#) to confirm that the function returns the following response. If you want to invoke this function using API Gateway, [create and configure a REST API](#).

```
{  
  "statusCode": 200,  
  "body": "{\"message\":\"hello world\"}"  
}
```

Deploy transpiled TypeScript code in Lambda with container images

You can deploy your TypeScript code to an AWS Lambda function as a Node.js [container image](#). AWS provides [base images](#) for Node.js to help you build the container image. These base images are preloaded with a language runtime and other components that are required to run the image on Lambda. AWS provides a Dockerfile for each of the base images to help with building your container image.

If you use a community or private enterprise base image, you must [add the Node.js runtime interface client \(RIC\)](#) to the base image to make it compatible with Lambda.

Lambda provides a runtime interface emulator for local testing. The AWS base images for Node.js include the runtime interface emulator. If you use an alternative base image, such as an Alpine Linux or Debian image, you can [build the emulator into your image](#) or [install it on your local machine](#).

Using a Node.js base image to build and package TypeScript function code

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Node.js 22.x

Creating an image from a base image

To create an image from an AWS base image for Lambda

1. On your local machine, create a project directory for your new function.
2. Create a new Node.js project with npm or a package manager of your choice.

```
npm init
```

3. Add the [@types/aws-lambda](#) and [esbuild](#) packages as development dependencies. The `@types/aws-lambda` package contains the type definitions for Lambda.

```
npm install -D @types/aws-lambda esbuild
```

4. Add a [build script](#) to the `package.json` file.

```
"scripts": {  
  "build": "esbuild index.ts --bundle --minify --sourcemap --platform=node --  
target=es2020 --outfile=dist/index.js"  
}
```

5. Create a new file called `index.ts`. Add the following sample code to the new file. This is the code for the Lambda function. The function returns a `hello world` message.

Note

The `import` statement imports the type definitions from [@types/aws-lambda](#). It does not import the `aws-lambda` NPM package, which is an unrelated third-party tool. For more information, see [aws-lambda](#) in the DefinitelyTyped GitHub repository.

```
import { Context, APIGatewayProxyResult, APIGatewayEvent } from 'aws-lambda';  
  
export const handler = async (event: APIGatewayEvent, context: Context):  
  Promise<APIGatewayProxyResult> => {  
  console.log(`Event: ${JSON.stringify(event, null, 2)}`);  
  console.log(`Context: ${JSON.stringify(context, null, 2)}`);  
  return {  
    statusCode: 200,  
    body: JSON.stringify({  
      message: 'hello world',  
    }),  
  };  
};
```

6. Create a new Dockerfile with the following configuration:
 - Set the `FROM` property to the URI of the base image.
 - Set the `CMD` argument to specify the Lambda function handler.

The following example Dockerfile uses a multi-stage build. The first step transpiles the TypeScript code into JavaScript. The second step produces a container image that contains only JavaScript files and production dependencies.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/nodejs:22 as builder
WORKDIR /usr/app
COPY package.json index.ts ./
RUN npm install
RUN npm run build

FROM public.ecr.aws/lambda/nodejs:22
WORKDIR ${LAMBDA_TASK_ROOT}
COPY --from=builder /usr/app/dist/* ./
CMD ["index.handler"]
```

7. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

1. Start the Docker image with the **docker run** command. In this example, `docker-image` is the image name and `test` is the tag.

```
docker run --platform linux/amd64 -p 9000:8080 docker-image:test
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

2. From a new terminal window, post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType "application/json"
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \  
  --function-name hello-world \  
  --package-type Image \  
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{  
  "ExecutedVersion": "$LATEST",  
  "StatusCode": 200  
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Using the Lambda context object to retrieve TypeScript function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides methods and properties that provide information about the invocation, function, and execution environment.

To enable type checking for the context object, you must add the [@types/aws-lambda](#) package as a development dependency and import the Context type. For more information, see [Type definitions for Lambda](#).

Context methods

- `getRemainingTimeInMillis()` – Returns the number of milliseconds left before the execution times out.

Context properties

- `functionName` – The name of the Lambda function.
- `functionVersion` – The [version](#) of the function.
- `invokedFunctionArn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `memoryLimitInMB` – The amount of memory that's allocated for the function.
- `awsRequestId` – The identifier of the invocation request.
- `logGroupName` – The log group for the function.
- `logStreamName` – The log stream for the function instance.
- `identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
 - `cognitoIdentityId` – The authenticated Amazon Cognito identity.
 - `cognitoIdentityPoolId` – The Amazon Cognito identity pool that authorized the invocation.
- `clientContext` – (mobile apps) Client context that's provided to Lambda by the client application.
 - `client.installation_id`

- `client.app_title`
 - `client.app_version_name`
 - `client.app_version_code`
 - `client.app_package_name`
 - `env.platform_version`
 - `env.platform`
 - `env.make`
 - `env.model`
 - `env.locale`
 - Custom – Custom values that are set by the client application.
- `callbackWaitsForEmptyEventLoop` – By default (`true`), when using a callback-based function handler, Lambda waits for the event loop to be empty after the callback runs before ending the function invoke. Set to `false` to send the response and end the invoke immediately after the callback runs instead of waiting for the event loop to be empty. Outstanding events continue to run during the next invocation. Note that Lambda supports callback-based function handlers for Node.js 22 and earlier runtimes only.

Example `index.ts` file

The following example function logs context information and returns the location of the logs.

Note

Before using this code in a Lambda function, you must add the [@types/aws-lambda](#) package as a development dependency. This package contains the type definitions for Lambda. For more information, see [Type definitions for Lambda](#).

```
import { Context } from 'aws-lambda';
export const lambdaHandler = async (event: string, context: Context): Promise<string>
=> {
    console.log('Remaining time: ', context.getRemainingTimeInMillis());
    console.log('Function name: ', context.functionName);
    return context.logStreamName;
};
```

Log and monitor TypeScript Lambda functions

AWS Lambda automatically monitors Lambda functions and sends log entries to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation and other output from your function's code to the log stream. For more information about CloudWatch Logs, see [Sending Lambda function logs to CloudWatch Logs](#).

To output logs from your function code, you can use methods on the [console object](#). For more detailed logging, you can use any logging library that writes to `stdout` or `stderr`.

Sections

- [Using logging tools and libraries](#)
- [Using Powertools for AWS Lambda \(TypeScript\) and AWS SAM for structured logging](#)
- [Using Powertools for AWS Lambda \(TypeScript\) and the AWS CDK for structured logging](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)

Using logging tools and libraries

[Powertools for AWS Lambda \(TypeScript\)](#) is a developer toolkit to implement Serverless best practices and increase developer velocity. The [Logger utility](#) provides a Lambda optimized logger which includes additional information about function context across all your functions with output structured as JSON. Use this utility to do the following:

- Capture key fields from the Lambda context, cold start and structures logging output as JSON
- Log Lambda invocation events when instructed (disabled by default)
- Print all the logs only for a percentage of invocations via log sampling (disabled by default)
- Append additional keys to structured log at any point in time
- Use a custom log formatter (Bring Your Own Formatter) to output logs in a structure compatible with your organization's Logging RFC

Using Powertools for AWS Lambda (TypeScript) and AWS SAM for structured logging

Follow the steps below to download, build, and deploy a sample Hello World TypeScript application with integrated [Powertools for AWS Lambda \(TypeScript\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Node.js 20 or later
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World TypeScript template.

```
sam init --app-template hello-world-powertools-typescript --name sam-app --package-type Zip --runtime nodejs24.x
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query
  'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name sam-app
```

The log output looks like this:

```
2025/01/31/[$LATEST]4d53e8d279824834a1ccd35511a4949c 2025-08-31T09:33:10.552000

```

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Managing log retention

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or configure a retention period after which CloudWatch automatically deletes the logs. To set up log retention, add the following to your AWS SAM template:

```
Resources:
  HelloWorldFunction:
    Type: AWS::Serverless::Function
    Properties:
      # Omitting other properties

  LogGroup:
    Type: AWS::Logs::LogGroup
    Properties:
      LogGroupName: !Sub "/aws/lambda/${HelloWorldFunction}"
      RetentionInDays: 7
```

Using Powertools for AWS Lambda (TypeScript) and the AWS CDK for structured logging

Follow the steps below to download, build, and deploy a sample Hello World TypeScript application with integrated [Powertools for AWS Lambda \(TypeScript\)](#) modules using the AWS CDK. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send

a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- Node.js 20 or later
- [AWS CLI version 2](#)
- [AWS CDK version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS CDK application

1. Create a project directory for your new application.

```
mkdir hello-world
cd hello-world
```

2. Initialize the app.

```
cdk init app --language typescript
```

3. Add the [@types/aws-lambda](#) package as a development dependency.

```
npm install -D @types/aws-lambda
```

4. Install the Powertools [Logger utility](#).

```
npm install @aws-lambda-powertools/logger
```

5. Open the **lib** directory. You should see a file called **hello-world-stack.ts**. Create new two new files in this directory: **hello-world.function.ts** and **hello-world.ts**.
6. Open **hello-world.function.ts** and add the following code to the file. This is the code for the Lambda function.

```
import { APIGatewayEvent, APIGatewayProxyResult, Context } from 'aws-lambda';
```

```
import { Logger } from '@aws-lambda-powertools/logger';
const logger = new Logger();

export const handler = async (event: APIGatewayEvent, context: Context):
  Promise<APIGatewayProxyResult> => {
  logger.info('This is an INFO log - sending HTTP 200 - hello world response');
  return {
    statusCode: 200,
    body: JSON.stringify({
      message: 'hello world',
    }),
  };
};
```

7. Open **hello-world.ts** and add the following code to the file. This contains the [NodejsFunction construct](#), which creates the Lambda function, configures environment variables for Powertools, and sets log retention to one week. It also includes the [LambdaRestApi construct](#), which creates the REST API.

```
import { Construct } from 'constructs';
import { NodejsFunction } from 'aws-cdk-lib/aws-lambda-nodejs';
import { LambdaRestApi } from 'aws-cdk-lib/aws-apigateway';
import { RetentionDays } from 'aws-cdk-lib/aws-logs';
import { CfnOutput } from 'aws-cdk-lib';

export class HelloWorld extends Construct {
  constructor(scope: Construct, id: string) {
    super(scope, id);
    const helloFunction = new NodejsFunction(this, 'function', {
      environment: {
        Powertools_SERVICE_NAME: 'helloWorld',
        LOG_LEVEL: 'INFO',
      },
      logRetention: RetentionDays.ONE_WEEK,
    });
    const api = new LambdaRestApi(this, 'apigw', {
      handler: helloFunction,
    });
    new CfnOutput(this, 'apiUrl', {
      exportName: 'apiUrl',
      value: api.url,
    });
  }
}
```

```
}
```

8. Open **hello-world-stack.ts**. This is the code that defines your [AWS CDK stack](#). Replace the code with the following:

```
import { Stack, StackProps } from 'aws-cdk-lib';
import { Construct } from 'constructs';
import { HelloWorld } from './hello-world';

export class HelloWorldStack extends Stack {
  constructor(scope: Construct, id: string, props?: StackProps) {
    super(scope, id, props);
    new HelloWorld(this, 'hello-world');
  }
}
```

9. Go back to the project directory.

```
cd hello-world
```

10. Deploy your application.

```
cdk deploy
```

11. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name HelloWorldStack --query
'Stacks[0].Outputs[?ExportName==`apiUrl`].OutputValue' --output text
```

12. Invoke the API endpoint:

```
curl <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

13. To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name HelloWorldStack
```

The log output looks like this:

```
2025/01/31/[$LATEST]2ca67f180dcd4d3e88b5d68576740c8e 2025-08-31T14:48:37.047000

  Duration: 35 ms Memory Size: 128 MB Max Memory Used: 57 MB Init Duration: 173.48
  ms
```

14. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
cdk destroy
```

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).

3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Tracing TypeScript code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of three SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for Node.js](#) – An SDK for generating and sending trace data to X-Ray.
- [Powertools for AWS Lambda \(TypeScript\)](#) – A developer toolkit to implement Serverless best practices and increase developer velocity.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

Sections

- [Using Powertools for AWS Lambda \(TypeScript\) and AWS SAM for tracing](#)
- [Using Powertools for AWS Lambda \(TypeScript\) and the AWS CDK for tracing](#)

Using Powertools for AWS Lambda (TypeScript) and AWS SAM for tracing

Follow the steps below to download, build, and deploy a sample Hello World TypeScript application with integrated [Powertools for AWS Lambda \(TypeScript\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Node.js
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World TypeScript template.

```
sam init --app-template hello-world-powertools-typescript --name sam-app --package-type Zip --runtime nodejs24.x --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query  
'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

```
XRay Event [revision 1] at (2023-01-31T11:29:40.527000) with id  
(1-11a2222-111a22222cb33de3b95daf9) and duration (0.483s)  
- 0.425s - sam-app/Prod [HTTP: 200]  
- 0.422s - Lambda [HTTP: 200]  
- 0.406s - sam-app-HelloWorldFunction-XYZv11a1bcde [HTTP: 200]  
- 0.172s - sam-app-HelloWorldFunction-XYZv11a1bcde  
- 0.179s - Initialization  
- 0.112s - Invocation  
- 0.052s - ## app.lambdaHandler  
- 0.001s - ### MySubSegment  
- 0.059s - Overhead
```

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

Using Powertools for AWS Lambda (TypeScript) and the AWS CDK for tracing

Follow the steps below to download, build, and deploy a sample Hello World TypeScript application with integrated [Powertools for AWS Lambda \(TypeScript\)](#) modules using the AWS CDK. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Node.js
- [AWS CLI version 2](#)
- [AWS CDK version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS Cloud Development Kit (AWS CDK) application

1. Create a project directory for your new application.

```
mkdir hello-world  
cd hello-world
```

2. Initialize the app.

```
cdk init app --language typescript
```

3. Add the [@types/aws-lambda](#) package as a development dependency.

```
npm install -D @types/aws-lambda
```

4. Install the Powertools [Tracer utility](#).

```
npm install @aws-lambda-powertools/tracer
```

5. Open the **lib** directory. You should see a file called **hello-world-stack.ts**. Create new two new files in this directory: **hello-world.function.ts** and **hello-world.ts**.
6. Open **hello-world.function.ts** and add the following code to the file. This is the code for the Lambda function.

```
import { APIGatewayEvent, APIGatewayProxyResult, Context } from 'aws-lambda';
import { Tracer } from '@aws-lambda-powertools/tracer';
const tracer = new Tracer();

export const handler = async (event: APIGatewayEvent, context: Context):
  Promise<APIGatewayProxyResult> => {
  // Get facade segment created by Lambda
  const segment = tracer.getSegment();

  // Create subsegment for the function and set it as active
  const handlerSegment = segment.addNewSubsegment(`## ${process.env._HANDLER}`);
  tracer.setSegment(handlerSegment);

  // Annotate the subsegment with the cold start and serviceName
  tracer.annotateColdStart();
  tracer.addServiceNameAnnotation();

  // Add annotation for the awsRequestId
  tracer.putAnnotation('awsRequestId', context.awsRequestId);
  // Create another subsegment and set it as active
  const subsegment = handlerSegment.addNewSubsegment('### MySubSegment');
  tracer.setSegment(subsegment);
  let response: APIGatewayProxyResult = {
    statusCode: 200,
    body: JSON.stringify({
      message: 'hello world',
```

```

    }),
  };
  // Close subsegments (the Lambda one is closed automatically)
  subsegment.close(); // (### MySubSegment)
  handlerSegment.close(); // (## index.handler)

  // Set the facade segment as active again (the one created by Lambda)
  tracer.setSegment(segment);
  return response;
};

```

7. Open **hello-world.ts** and add the following code to the file. This contains the [NodejsFunction construct](#), which creates the Lambda function, configures environment variables for Powertools, and sets log retention to one week. It also includes the [LambdaRestApi construct](#), which creates the REST API.

```

import { Construct } from 'constructs';
import { NodejsFunction } from 'aws-cdk-lib/aws-lambda-nodejs';
import { LambdaRestApi } from 'aws-cdk-lib/aws-apigateway';
import { CfnOutput } from 'aws-cdk-lib';
import { Tracing } from 'aws-cdk-lib/aws-lambda';

export class HelloWorld extends Construct {
  constructor(scope: Construct, id: string) {
    super(scope, id);
    const helloFunction = new NodejsFunction(this, 'function', {
      environment: {
        POWERTOOLS_SERVICE_NAME: 'helloWorld',
      },
      tracing: Tracing.ACTIVE,
    });
    const api = new LambdaRestApi(this, 'apigw', {
      handler: helloFunction,
    });
    new CfnOutput(this, 'apiUrl', {
      exportName: 'apiUrl',
      value: api.url,
    });
  }
}

```

8. Open **hello-world-stack.ts**. This is the code that defines your [AWS CDK stack](#). Replace the code with the following:

```
import { Stack, StackProps } from 'aws-cdk-lib';
import { Construct } from 'constructs';
import { HelloWorld } from './hello-world';

export class HelloWorldStack extends Stack {
  constructor(scope: Construct, id: string, props?: StackProps) {
    super(scope, id, props);
    new HelloWorld(this, 'hello-world');
  }
}
```

9. Deploy your application.

```
cd ..
cdk deploy
```

10. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name HelloWorldStack --query
'Stacks[0].Outputs[?ExportName==`apiUrl`].OutputValue' --output text
```

11. Invoke the API endpoint:

```
curl <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

12. To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

```
XRay Event [revision 1] at (2023-01-31T11:50:06.997000) with id
(1-11a2222-111a22222cb33de3b95daf9) and duration (0.449s)
- 0.350s - HelloWorldStack-helloworldfunction111A2BCD-Xyzv11a1bcde [HTTP: 200]
- 0.157s - HelloWorldStack-helloworldfunction111A2BCD-Xyzv11a1bcde
- 0.169s - Initialization
```

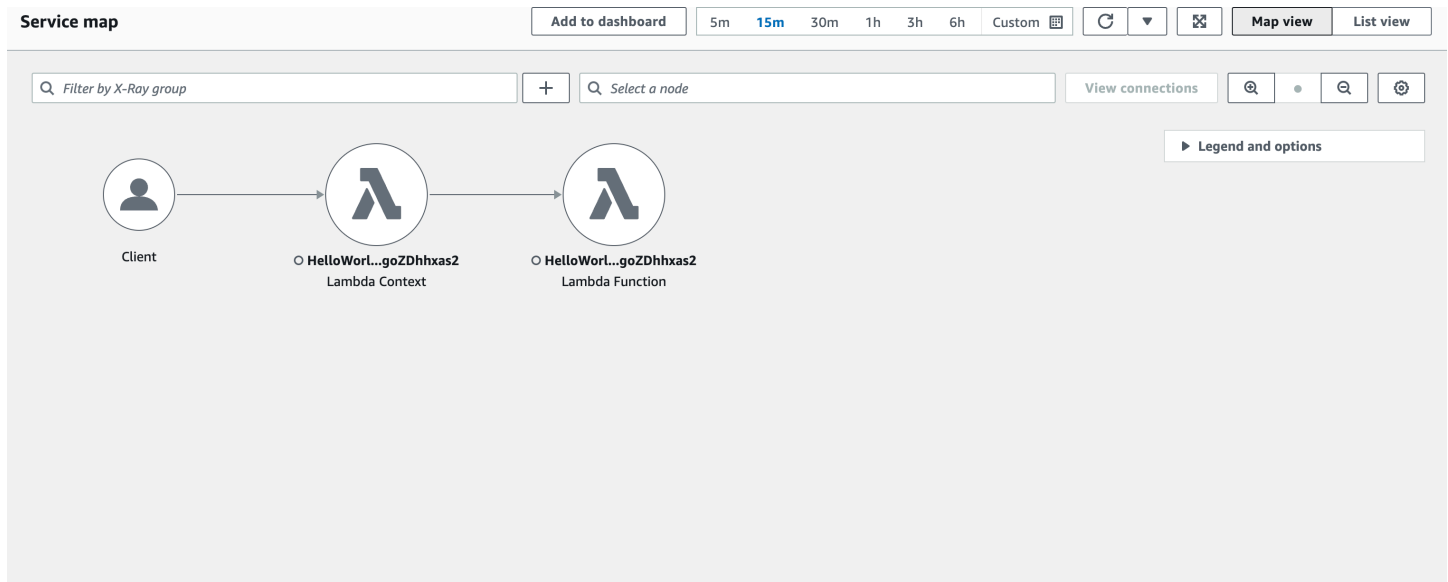

- 0.058s - Invocation
- 0.055s - ## index.handler
 - 0.000s - ### MySubSegment
- 0.099s - Overhead

13. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
cdk destroy
```

Interpreting an X-Ray trace

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray trace map](#) provides information about your application and all its components. The following example shows a trace from the sample application:

Building Lambda functions with Python

You can run Python code in AWS Lambda. Lambda provides [runtimes](#) for Python that run your code to process events. Your code runs in an environment that includes the SDK for Python (Boto3), with credentials from an AWS Identity and Access Management (IAM) role that you manage. To learn more about the SDK versions included with the Python runtimes, see [the section called “Runtime-included SDK versions”](#).

Lambda supports the following Python runtimes.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
Python 3.14	python3.14	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
Python 3.13	python3.13	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
Python 3.12	python3.12	Amazon Linux 2023	Oct 31, 2028	Nov 30, 2028	Jan 10, 2029
Python 3.11	python3.11	Amazon Linux 2	Jun 30, 2027	Jul 31, 2027	Aug 31, 2027
Python 3.10	python3.10	Amazon Linux 2	Oct 31, 2026	Nov 30, 2026	Jan 15, 2027

To create a Python function

1. Open the [Lambda console](#).
2. Choose **Create function**.
3. Configure the following settings:
 - **Function name:** Enter a name for the function.
 - **Runtime:** Choose **Python 3.14**.

4. Choose **Create function**.

The console creates a Lambda function with a single source file named `lambda_function`. You can edit this file and add more files in the built-in code editor. In the **DEPLOY** section, choose **Deploy** to update your function's code. Then, to run your code, choose **Create test event** in the **TEST EVENTS** section.

Your Lambda function comes with a CloudWatch Logs log group. The function runtime sends details about each invocation to CloudWatch Logs. It relays any [logs that your function outputs](#) during invocation. If your function returns an error, Lambda formats the error and returns it to the invoker.

- [Instrumenting Python code in AWS Lambda](#)

Runtime-included SDK versions

The version of the AWS SDK included in the Python runtime depends on the runtime version and your AWS Region. To find the version of the SDK included in the runtime you're using, create a Lambda function with the following code.

```
import boto3
import botocore
```

```
def lambda_handler(event, context):  
    print(f'boto3 version: {boto3.__version__}')  
    print(f'botocore version: {botocore.__version__}')
```

Disabled Python features

The following table lists Python features which are disabled in the Lambda managed runtimes and container base images for Python. These features must be enabled when the Python runtime executable is compiled and cannot be enabled by using an execution-time flag. To use these features in Lambda, you can deploy your own Python runtime build with these features enabled, using a [container image](#) or [custom runtime](#).

Python feature	Affected Python versions	Status
Just-in-Time (JIT) compiler	Python 3.13 and later	The JIT compiler is experimental and is not recommended for production workloads. It is therefore disabled in the Lambda Python runtimes.
Free-threading	Python 3.13 and later	Free threading (option to disable the global interpreter lock) is disabled in Lambda Python builds due to the performance impact on single-threaded code.

Response format

In Python 3.12 and later Python runtimes, functions return Unicode characters as part of their JSON response. Earlier Python runtimes return escaped sequences for Unicode characters in responses. For example, in Python 3.11, if you return a Unicode string such as "こんにちは", it escapes the Unicode characters and returns "\u3053\u3093\u306b\u3061\u306f". The Python 3.12 runtime returns the original "こんにちは".

Using Unicode responses reduces the size of Lambda responses, making it easier to fit larger responses into the 6 MB maximum payload size for synchronous functions. In the previous example, the escaped version is 32 bytes—compared to 17 bytes with the Unicode string.

When you upgrade to Python 3.12 or later Python runtimes, you might need to adjust your code to account for the new response format. If the caller expects escaped Unicode, you must either add code to the returning function to escape the Unicode manually, or adjust the caller to handle the Unicode return.

Graceful shutdown for extensions

Python 3.12 and later Python runtimes offer improved graceful shutdown capabilities for functions with [external extensions](#). When Lambda shuts down an execution environment, it sends a SIGTERM signal to the runtime and then a SHUTDOWN event to each registered external extension. You can catch the SIGTERM signal in your Lambda function and clean up resources such as database connections that were created by the function.

To learn more about the execution environment lifecycle, see [Understanding the Lambda execution environment lifecycle](#). For examples of how to use graceful shutdown with extensions, see the [AWS Samples GitHub repository](#).

Define Lambda function handler in Python

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in Python, including naming conventions, valid handler signatures, and code best practices. This page also includes an example of a Python Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (Amazon S3) bucket.

Topics

- [Example Python Lambda function code](#)
- [Handler naming conventions](#)
- [Using the Lambda event object](#)
- [Accessing and using the Lambda context object](#)
- [Valid handler signatures for Python handlers](#)
- [Returning a value](#)
- [Using the AWS SDK for Python \(Boto3\) in your handler](#)
- [Accessing environment variables](#)
- [Code best practices for Python Lambda functions](#)

Example Python Lambda function code

The following example Python Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket:

Example Python Lambda function

```
import json
import os
import logging
import boto3

# Initialize the S3 client outside of the handler
s3_client = boto3.client('s3')
```

```
# Initialize the logger
logger = logging.getLogger()
logger.setLevel("INFO")

def upload_receipt_to_s3(bucket_name, key, receipt_content):
    """Helper function to upload receipt to S3"""

    try:
        s3_client.put_object(
            Bucket=bucket_name,
            Key=key,
            Body=receipt_content
        )
    except Exception as e:
        logger.error(f"Failed to upload receipt to S3: {str(e)}")
        raise

def lambda_handler(event, context):
    """
    Main Lambda handler function
    Parameters:
        event: Dict containing the Lambda function event data
        context: Lambda runtime context
    Returns:
        Dict containing status message
    """
    try:
        # Parse the input event
        order_id = event['Order_id']
        amount = event['Amount']
        item = event['Item']

        # Access environment variables
        bucket_name = os.environ.get('RECEIPT_BUCKET')
        if not bucket_name:
            raise ValueError("Missing required environment variable RECEIPT_BUCKET")

        # Create the receipt content and key destination
        receipt_content = (
            f"OrderID: {order_id}\n"
            f"Amount: ${amount}\n"
            f"Item: {item}"
        )
        key = f"receipts/{order_id}.txt"
```

```
# Upload the receipt to S3
upload_receipt_to_s3(bucket_name, key, receipt_content)

logger.info(f"Successfully processed order {order_id} and stored receipt in S3
bucket {bucket_name}")

return {
    "statusCode": 200,
    "message": "Receipt processed successfully"
}

except Exception as e:
    logger.error(f"Error processing order: {str(e)}")
    raise
```

This file contains the following sections of code:

- `import` block: Use this block to include libraries that your Lambda function requires.
- Global initialization of SDK client and logger: Including initialization code outside of the handler takes advantage of [execution environment](#) re-use to improve the performance of your function. See [the section called “Code best practices for Python Lambda functions”](#) to learn more.
- `def upload_receipt_to_s3(bucket_name, key, receipt_content)`: This is a helper function that's called by the main `lambda_handler` function.
- `def lambda_handler(event, context)`: This is the **main handler function** for your code, which contains your main application logic. When Lambda invokes your function handler, the [Lambda runtime](#) passes two arguments to the function, the [event object](#) that contains data for your function to process and the [context object](#) that contains information about the function invocation.

Handler naming conventions

The function handler name defined at the time that you create a Lambda function is derived from:

- The name of the file in which the Lambda handler function is located.
- The name of the Python handler function.

In the example above, if the file is named `lambda_function.py`, the handler would be specified as `lambda_function.lambda_handler`. This is the default handler name given to functions you create using the Lambda console.

If you create a function in the console using a different file name or function handler name, you must edit the default handler name.

To change the function handler name (console)

1. Open the [Functions](#) page of the Lambda console and choose your function.
2. Choose the **Code** tab.
3. Scroll down to the **Runtime settings** pane and choose **Edit**.
4. In **Handler**, enter the new name for your function handler.
5. Choose **Save**.

Using the Lambda event object

When Lambda invokes your function, it passes an [event object](#) argument to the function handler. JSON objects are the most common event format for Lambda functions. In the code example in the previous section, the function expects an input in the following format:

```
{
  "Order_id": "12345",
  "Amount": 199.99,
  "Item": "Wireless Headphones"
}
```

If your function is invoked by another AWS service, the input event is also a JSON object. The exact format of the event object depends on the service that's invoking your function. To see the event format for a particular service, refer to the appropriate page in the [Integrating other services](#) chapter.

If the input event is in the form of a JSON object, the Lambda runtime converts the object to a Python dictionary. To assign values in the input JSON to variables in your code, use the standard Python dictionary methods as illustrated in the example code.

You can also pass data into your function as a JSON array, or as any of the other valid JSON data types. The following table defines how the Python runtime converts these JSON types.

JSON data type	Python data type
object	dictionary (dict)
array	list (list)
number	integer (int) or floating point number (float)
string	string (str)
Boolean	Boolean (bool)
null	NoneType (NoneType)

Accessing and using the Lambda context object

The Lambda context object contains information about the function invocation and execution environment. Lambda passes the context object to your function automatically when it's invoked. You can use the context object to output information about your function's invocation for monitoring purposes.

The context object is a Python class that's defined in the [Lambda runtime interface client](#). To return the value of any of the context object properties, use the corresponding method on the context object. For example, the following code snippet assigns the value of the `aws_request_id` property (the identifier for the invocation request) to a variable named `request`.

```
request = context.aws_request_id
```

To learn more about using the Lambda context object, and to see a complete list of the available methods and properties, see [the section called "Context"](#).

Valid handler signatures for Python handlers

When defining your handler function in Python, the function must take two arguments. The first of these arguments is the Lambda [event object](#) and the second one is the Lambda [context object](#). By convention, these input arguments are usually named `event` and `context`, but you can give them any names you wish. If you declare your handler function with a single input argument,

Lambda will raise an error when it attempts to run your function. The most common way to declare a handler function in Python is as follows:

```
def lambda_handler(event, context):
```

You can also use Python type hints in your function declaration, as shown in the following example:

```
from typing import Dict, Any

def lambda_handler(event: Dict[str, Any], context: Any) -> Dict[str, Any]:
```

To use specific AWS typing for events generated by other AWS services and for the context object, add the `aws-lambda-typing` package to your function's deployment package. You can install this library in your development environment by running **`pip install aws-lambda-typing`**. The following code snippet shows how to use AWS-specific type hints. In this example, the expected event is an Amazon S3 event.

```
from aws_lambda_typing.events import S3Event
from aws_lambda_typing.context import Context
from typing import Dict, Any

def lambda_handler(event: S3Event, context: Context) -> Dict[str, Any]:
```

You can't use the Python `async` function type for your handler function.

Returning a value

Optionally, a handler can return a value, which must be JSON serializable. Common return types include `dict`, `list`, `str`, `int`, `float`, and `bool`.

What happens to the returned value depends on the [invocation type](#) and the [service](#) that invoked the function. For example:

- If you use the `RequestResponse` invocation type to [invoke a Lambda function synchronously](#), Lambda returns the result of the Python function call to the client invoking the Lambda function (in the HTTP response to the invocation request, serialized into JSON). For example, AWS Lambda console uses the `RequestResponse` invocation type, so when you invoke the function on the console, the console will display the returned value.

- If the handler returns objects that can't be serialized by `json.dumps`, the runtime returns an error.
- If the handler returns `None`, as Python functions without a `return` statement implicitly do, the runtime returns `null`.
- If you use the Event invocation type (an [asynchronous invocation](#)), the value is discarded.

In the example code, the handler returns the following Python dictionary:

```
{
    "statusCode": 200,
    "message": "Receipt processed successfully"
}
```

The Lambda runtime serializes this dictionary and returns it to the client that invoked the function as a JSON string.

 **Note**

In Python 3.9 and later releases, Lambda includes the `requestId` of the invocation in the error response.

Using the AWS SDK for Python (Boto3) in your handler

Often, you'll use Lambda functions to interact with other AWS services and resources. The simplest way to interface with these resources is to use the AWS SDK for Python (Boto3). All [supported Lambda Python runtimes](#) include a version of the SDK for Python. However, we strongly recommend that you include the SDK in your function's deployment package if your code needs to use it. Including the SDK in your deployment package gives you full control over your dependencies and reduces the risk of version misalignment issues with other libraries. See [the section called "Runtime dependencies in Python"](#) and [the section called "Backward compatibility"](#) to learn more.

To use the SDK for Python in your Lambda function, add the following statement to the import block at the beginning of your function code:

```
import boto3
```

Use the `pip install` command to add the `boto3` library to your function's deployment package. For detailed instructions on how to add dependencies to a `.zip` deployment package, see [the section called “Creating a .zip deployment package with dependencies”](#). To learn more about adding dependencies to Lambda functions deployed as container images, see [the section called “Creating an image from a base image”](#) or [the section called “Creating an image from an alternative base image”](#).

When using `boto3` in your code, you don't need to provide any credentials to initialize a client. For example, in the example code, we use the following line of code to initialize an Amazon S3 client:

```
# Initialize the S3 client outside of the handler
s3_client = boto3.client('s3')
```

With Python, Lambda automatically creates environment variables with credentials. The `boto3` SDK checks your function's environment variables for these credentials during initialization.

Accessing environment variables

In your handler code, you can reference [environment variables](#) by using the `os.environ.get` method. In the example code, we reference the defined `RECEIPT_BUCKET` environment variable using the following line of code:

```
# Access environment variables
bucket_name = os.environ.get('RECEIPT_BUCKET')
```

Don't forget to include an `import os` statement in the import block at the beginning of your code.

Code best practices for Python Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function. For example, in Python, this may look like:

```
def lambda_handler(event, context):
    foo = event['foo']
    bar = event['bar']
```

```
result = my_lambda_function(foo, bar)

def my_lambda_function(foo, bar):
    // MyLambdaFunction logic here
```

- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. For the Node.js and Python runtimes, these include the AWS SDKs. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation.

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of

function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Working with .zip file archives for Python Lambda functions

Your AWS Lambda function's code comprises a .py file containing your function's handler code, together with any additional packages and modules your code depends on. To deploy this function code to Lambda, you use a *deployment package*. This package may either be a .zip file archive or a container image. For more information about using container images with Python, see [Deploy Python Lambda functions with container images](#).

To create your deployment package as .zip file archive, you can use your command-line tool's built-in .zip file archive utility, or any other .zip file utility such as [7zip](#). The examples shown in the following sections assume you're using a command-line zip tool in a Linux or MacOS environment. To use the same commands in Windows, you can [install the Windows Subsystem for Linux](#) to get a Windows-integrated version of Ubuntu and Bash.

Note that Lambda uses POSIX file permissions, so you may need to [set permissions for the deployment package folder](#) before you create the .zip file archive.

Topics

- [Runtime dependencies in Python](#)
- [Creating a .zip deployment package with no dependencies](#)
- [Creating a .zip deployment package with dependencies](#)
- [Dependency search path and runtime-included libraries](#)
- [Using __pycache__ folders](#)
- [Creating .zip deployment packages with native libraries](#)
- [Creating and updating Python Lambda functions using .zip files](#)

Runtime dependencies in Python

For Lambda functions that use the Python runtime, a dependency can be any Python package or module. When you deploy your function using a .zip archive, you can either add these dependencies to your .zip file with your function code or use a [Lambda layer](#). A layer is a separate .zip file that can contain additional code and other content. To learn more about using Lambda layers in Python, see [the section called "Layers"](#).

The Lambda Python runtimes include the AWS SDK for Python (Boto3) and its dependencies. Lambda provides the SDK in the runtime for deployment scenarios where you are unable to add your own dependencies. These scenarios include creating functions in the console using the

built-in code editor or using inline functions in AWS Serverless Application Model (AWS SAM) or CloudFormation templates.

Lambda periodically updates the libraries in the Python runtime to include the latest updates and security patches. If your function uses the version of the Boto3 SDK included in the runtime but your deployment package includes SDK dependencies, this can cause version misalignment issues. For example, your deployment package could include the SDK dependency `urllib3`. When Lambda updates the SDK in the runtime, compatibility issues between the new version of the runtime and the version of `urllib3` in your deployment package can cause your function to fail.

Important

To maintain full control over your dependencies and to avoid possible version misalignment issues, we recommend you add all of your function's dependencies to your deployment package, even if versions of them are included in the Lambda runtime. This includes the Boto3 SDK.

To find out which version of the SDK for Python (Boto3) is included in the runtime you're using, see [the section called "Runtime-included SDK versions"](#).

Under the [AWS shared responsibility model](#), you are responsible for the management of any dependencies in your functions' deployment packages. This includes applying updates and security patches. To update dependencies in your function's deployment package, first create a new `.zip` file and then upload it to Lambda. See [Creating a .zip deployment package with dependencies](#) and [Creating and updating Python Lambda functions using .zip files](#) for more information.

Creating a .zip deployment package with no dependencies

If your function code has no dependencies, your `.zip` file contains only the `.py` file with your function's handler code. Use your preferred zip utility to create a `.zip` file with your `.py` file at the root. If the `.py` file is not at the root of your `.zip` file, Lambda won't be able to run your code.

To learn how to deploy your `.zip` file to create a new Lambda function or update an existing one, see [Creating and updating Python Lambda functions using .zip files](#).

Creating a .zip deployment package with dependencies

If your function code depends on additional packages or modules, you can either add these dependencies to your `.zip` file with your function code or [use a Lambda layer](#). The instructions

in this section show you how to include your dependencies in your .zip deployment package. For Lambda to run your code, the .py file containing your handler code and all of your function's dependencies must be installed at the root of the .zip file.

Suppose your function code is saved in a file named `lambda_function.py`. The following example CLI commands create a .zip file named `my_deployment_package.zip` containing your function code and its dependencies. You can either install your dependencies directly to a folder in your project directory or use a Python virtual environment.

To create the deployment package (project directory)

1. Navigate to the project directory containing your `lambda_function.py` source code file. In this example, the directory is named `my_function`.

```
cd my_function
```

2. Create a new directory named `package` into which you will install your dependencies.

```
mkdir package
```

Note that for a .zip deployment package, Lambda expects your source code and its dependencies all to be at the root of the .zip file. However, installing dependencies directly in your project directory can introduce a large number of new files and folders and make navigating around your IDE difficult. You create a separate package directory here to keep your dependencies separate from your source code.

3. Install your dependencies in the package directory. The example below installs the Boto3 SDK from the Python Package Index using `pip`. If your function code uses Python packages you have created yourself, save them in the package directory.

```
pip install --target ./package boto3
```

4. Create a .zip file with the installed libraries at the root.

```
cd package  
zip -r ../my_deployment_package.zip .
```

This generates a `my_deployment_package.zip` file in your project directory.

5. Add the `lambda_function.py` file to the root of the .zip file

```
cd ..  
zip my_deployment_package.zip lambda_function.py
```

Your .zip file should have a flat directory structure, with your function's handler code and all your dependency folders installed at the root as follows.

```
my_deployment_package.zip  
|- bin  
|  |-jp.py  
|- boto3  
|  |-compat.py  
|  |-data  
|  |-docs  
...  
|- lambda_function.py
```

If the .py file containing your function's handler code is not at the root of your .zip file, Lambda will not be able to run your code.

To create the deployment package (virtual environment)

1. Create and activate a virtual environment in your project directory. In this example the project directory is named `my_function`.

```
~$ cd my_function  
~/my_function$ python3.14 -m venv my_virtual_env  
~/my_function$ source ./my_virtual_env/bin/activate
```

2. Install your required libraries using pip. The following example installs the Boto3 SDK

```
(my_virtual_env) ~/my_function$ pip install boto3
```

3. Use `pip show` to find the location in your virtual environment where pip has installed your dependencies.

```
(my_virtual_env) ~/my_function$ pip show <package_name>
```

The folder in which pip installs your libraries may be named `site-packages` or `dist-packages`. This folder may be located in either the `lib/python3.x` or `lib64/python3.x` directory (where `python3.x` represents the version of Python you are using).

4. Deactivate the virtual environment

```
(my_virtual_env) ~/my_function$ deactivate
```

5. Navigate into the directory containing the dependencies you installed with pip and create a .zip file in your project directory with the installed dependencies at the root. In this example, pip has installed your dependencies in the `my_virtual_env/lib/python3.14/site-packages` directory.

```
~/my_function$ cd my_virtual_env/lib/python3.14/site-packages
~/my_function/my_virtual_env/lib/python3.14/site-packages$ zip -r ../../../../
my_deployment_package.zip .
```

6. Navigate to the root of your project directory where the .py file containing your handler code is located and add that file to the root of your .zip package. In this example, your function code file is named `lambda_function.py`.

```
~/my_function/my_virtual_env/lib/python3.14/site-packages$ cd ../../../../
~/my_function$ zip my_deployment_package.zip lambda_function.py
```

Dependency search path and runtime-included libraries

When you use an `import` statement in your code, the Python runtime searches the directories in its search path until it finds the module or package. By default, the first location the runtime searches is the directory into which your .zip deployment package is decompressed and mounted (`/var/task`). If you include a version of a runtime-included library in your deployment package, your version will take precedence over the version that's included in the runtime. Dependencies in your deployment package also have precedence over dependencies in layers.

When you add a dependency to a layer, Lambda extracts this to `/opt/python/lib/python3.x/site-packages` (where `python3.x` represents the version of the runtime you're using) or `/opt/python`. In the search path, these directories have precedence over the directories containing the runtime-included libraries and pip-installed libraries (`/var/runtime` and `/var/lang/`

lib/python3.x/site-packages). Libraries in function layers therefore have precedence over versions included in the runtime.

 **Note**

In the Python 3.11 managed runtime and base image, the AWS SDK and its dependencies are installed in the `/var/lang/lib/python3.11/site-packages` directory.

You can see the full search path for your Lambda function by adding the following code snippet.

```
import sys

search_path = sys.path
print(search_path)
```

 **Note**

Because dependencies in your deployment package or layers take precedence over runtime-included libraries, this can cause version misalignment problems if you include an SDK dependency such as `urllib3` in your package without including the SDK as well. If you deploy your own version of a Boto3 dependency, you must also deploy Boto3 as a dependency in your deployment package. We recommend that you package all of your function's dependencies, even if versions of them are included in the runtime.

You can also add dependencies in a separate folder inside your `.zip` package. For example, you might add a version of the Boto3 SDK to a folder in your `.zip` package called `common`. When your `.zip` package is decompressed and mounted, this folder is placed inside the `/var/task` directory. To use a dependency from a folder in your `.zip` deployment package in your code, use an `import from` statement. For example, to use a version of Boto3 from a folder named `common` in your `.zip` package, use the following statement.

```
from common import boto3
```

Using `__pycache__` folders

We recommend that you don't include `__pycache__` folders in your function's deployment package. Python bytecode that's compiled on a build machine with a different architecture or operating system might not be compatible with the Lambda execution environment.

Creating .zip deployment packages with native libraries

If your function uses only pure Python packages and modules, you can use the `pip install` command to install your dependencies on any local build machine and create your .zip file. Many popular Python libraries, including NumPy and Pandas, are not pure Python and contain code written in C or C++. When you add libraries containing C/C++ code to your deployment package, you must build your package correctly to ensure that it's compatible with the Lambda execution environment.

Most packages available on the Python Package Index ([PyPI](#)) are available as “wheels” (.whl files). A .whl file is a type of ZIP file which contains a built distribution with pre-compiled binaries for a particular operating system and instruction set architecture. To make your deployment package compatible with Lambda, you install the wheel for Linux operating systems and your function's instruction set architecture.

Some packages may only be available as source distributions. For these packages, you need to compile and build the C/C++ components yourself.

To see what distributions are available for your required package, do the following:

1. Search for the name of the package on the [Python Package Index main page](#).
2. Choose the version of the package you want to use.
3. Choose **Download files**.

Working with built distributions (wheels)

To download a wheel that's compatible with Lambda, you use the `pip --platform` option.

If your Lambda function uses the **x86_64** instruction set architecture, run the following `pip install` command to install a compatible wheel in your package directory. Replace `--python 3.x` with the version of the Python runtime you are using.

```
pip install \
```

```
--platform manylinux2014_x86_64 \  
--target=package \  
--implementation cp \  
--python-version 3.x \  
--only-binary=:all: --upgrade \  
<package_name>
```

If your function uses the **arm64** instruction set architecture, run the following command. Replace `--python 3.x` with the version of the Python runtime you are using.

```
pip install \  
--platform manylinux2014_aarch64 \  
--target=package \  
--implementation cp \  
--python-version 3.x \  
--only-binary=:all: --upgrade \  
<package_name>
```

Working with source distributions

If your package is only available as a source distribution, you need to build the C/C++ libraries yourself. To make your package compatible with the Lambda execution environment, you need to build it in an environment that uses the same Amazon Linux operating system. You can do this by building your package in an Amazon Elastic Compute Cloud (Amazon EC2) Linux instance.

To learn how to launch and connect to an Amazon EC2 Linux instance, see [Get started with Amazon EC2](#) in the *Amazon EC2 User Guide*.

Creating and updating Python Lambda functions using .zip files

After you have created your .zip deployment package, you can use it to create a new Lambda function or update an existing one. You can deploy your .zip package using the Lambda console, the AWS Command Line Interface, and the Lambda API. You can also create and update Lambda functions using AWS Serverless Application Model (AWS SAM) and CloudFormation.

The maximum size for a .zip deployment package for Lambda is 250 MB (unzipped). Note that this limit applies to the combined size of all the files you upload, including any Lambda layers.

The Lambda runtime needs permission to read the files in your deployment package. In Linux permissions octal notation, Lambda needs 644 permissions for non-executable files (rw-r--r--) and 755 permissions (rwxr-xr-x) for directories and executable files.

In Linux and MacOS, use the `chmod` command to change file permissions on files and directories in your deployment package. For example, to give a non-executable file the correct permissions, run the following command.

```
chmod 644 <filepath>
```

To change file permissions in Windows, see [Set, View, Change, or Remove Permissions on an Object](#) in the Microsoft Windows documentation.

Note

If you don't grant Lambda the permissions it needs to access directories in your deployment package, Lambda sets the permissions for those directories to 755 (rwxr-xr-x).

Creating and updating functions with .zip files using the console

To create a new function, you must first create the function in the console, then upload your .zip archive. To update an existing function, open the page for your function, then follow the same procedure to add your updated .zip file.

If your .zip file is less than 50MB, you can create or update a function by uploading the file directly from your local machine. For .zip files greater than 50MB, you must upload your package to an Amazon S3 bucket first. For instructions on how to upload a file to an Amazon S3 bucket using the AWS Management Console, see [Getting started with Amazon S3](#). To upload files using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

To create a new function (console)

1. Open the [Functions page](#) of the Lambda console and choose **Create Function**.
2. Choose **Author from scratch**.

3. Under **Basic information**, do the following:
 - a. For **Function name**, enter the name for your function.
 - b. For **Runtime**, select the runtime you want to use.
 - c. (Optional) For **Architecture**, choose the instruction set architecture for your function. The default architecture is x86_64. Ensure that the .zip deployment package for your function is compatible with the instruction set architecture you select.
4. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing one.
5. Choose **Create function**. Lambda creates a basic 'Hello world' function using your chosen runtime.

To upload a .zip archive from your local machine (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload the .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip file**.
5. To upload the .zip file, do the following:
 - a. Select **Upload**, then select your .zip file in the file chooser.
 - b. Choose **Open**.
 - c. Choose **Save**.

To upload a .zip archive from an Amazon S3 bucket (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload a new .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **Amazon S3 location**.
5. Paste the Amazon S3 link URL of your .zip file and choose **Save**.

Updating .zip file functions using the console code editor

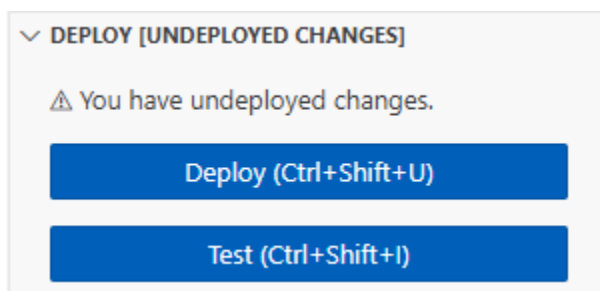

For some functions with .zip deployment packages, you can use the Lambda console's built-in code editor to update your function code directly. To use this feature, your function must meet the following criteria:

- Your function must use one of the interpreted language runtimes (Python, Node.js, or Ruby)
- Your function's deployment package must be smaller than 50 MB (unzipped).

Function code for functions with container image deployment packages cannot be edited directly in the console.

To update function code using the console code editor

1. Open the [Functions page](#) of the Lambda console and select your function.
2. Select the **Code** tab.
3. In the **Code source** pane, select your source code file and edit it in the integrated code editor.
4. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Creating and updating functions with .zip files using the AWS CLI

You can use the [AWS CLI](#) to create a new function or to update an existing one using a .zip file. Use the [create-function](#) and [update-function-code](#) commands to deploy your .zip package. If your .zip file is smaller than 50MB, you can upload the .zip package from a file location on your local build machine. For larger files, you must upload your .zip package from an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

If you upload your .zip file from an Amazon S3 bucket using the AWS CLI, the bucket must be located in the same AWS Region as your function.

To create a new function using a .zip file with the AWS CLI, you must specify the following:

- The name of your function (`--function-name`)
- Your function's runtime (`--runtime`)
- The Amazon Resource Name (ARN) of your function's [execution role](#) (`--role`)
- The name of the handler method in your function code (`--handler`)

You must also specify the location of your .zip file. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda create-function --function-name myFunction \  
--runtime python3.14 --handler lambda_function.lambda_handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--code` option as shown in the following example command. You only need to use the `S3ObjectVersion` parameter for versioned objects.

```
aws lambda create-function --function-name myFunction \  
--runtime python3.14 --handler lambda_function.lambda_handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--code S3Bucket=amzn-s3-demo-  
bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion
```

To update an existing function using the CLI, you specify the the name of your function using the `--function-name` parameter. You must also specify the location of the .zip file you want to use to update your function code. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda update-function-code --function-name myFunction \  
--zip-file fileb://myFunction.zip
```

```
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--s3-bucket` and `--s3-key` options as shown in the following example command. You only need to use the `--s3-object-version` parameter for versioned objects.

```
aws lambda update-function-code --function-name myFunction \  
--s3-bucket amzn-s3-demo-bucket --s3-key myFileName.zip --s3-object-version myObject  
Version
```

Creating and updating functions with .zip files using the Lambda API

To create and update functions using a .zip file archive, use the following API operations:

- [CreateFunction](#)
- [UpdateFunctionCode](#)

Creating and updating functions with .zip files using AWS SAM

The AWS Serverless Application Model (AWS SAM) is a toolkit that helps streamline the process of building and running serverless applications on AWS. You define the resources for your application in a YAML or JSON template and use the AWS SAM command line interface (AWS SAM CLI) to build, package, and deploy your applications. When you build a Lambda function from an AWS SAM template, AWS SAM automatically creates a .zip deployment package or container image with your function code and any dependencies you specify. To learn more about using AWS SAM to build and deploy Lambda functions, see [Getting started with AWS SAM](#) in the *AWS Serverless Application Model Developer Guide*.

You can also use AWS SAM to create a Lambda function using an existing .zip file archive. To create a Lambda function using AWS SAM, you can save your .zip file in an Amazon S3 bucket or in a local folder on your build machine. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your AWS SAM template, the `AWS::Serverless::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - set to `Zip`
- `CodeUri` - set to the function code's Amazon S3 URI, path to local folder, or [FunctionCode](#) object

- Runtime - Set to your chosen runtime

With AWS SAM, if your .zip file is larger than 50MB, you don't need to upload it to an Amazon S3 bucket first. AWS SAM can upload .zip packages up to the maximum allowed size of 250MB (unzipped) from a location on your local build machine.

To learn more about deploying functions using .zip file in AWS SAM, see [AWS::Serverless::Function](#) in the *AWS SAM Developer Guide*.

Creating and updating functions with .zip files using CloudFormation

You can use CloudFormation to create a Lambda function using a .zip file archive. To create a Lambda function from a .zip file, you must first upload your file to an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

For Node.js and Python runtimes, you can also provide inline source code in your CloudFormation template. CloudFormation then creates a .zip file containing your code when you build your function.

Using an existing .zip file

In your CloudFormation template, the `AWS::Lambda::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- PackageType - Set to Zip
- Code - Enter the Amazon S3 bucket name and the .zip file name in the S3Bucket and S3Key fields
- Runtime - Set to your chosen runtime

Creating a .zip file from inline code

You can declare simple functions written in Python or Node.js inline in an CloudFormation template. Because the code is embedded in YAML or JSON, you can't add any external dependencies to your deployment package. This means your function has to use the version of the AWS SDK that's included in the runtime. The requirements of the template, such as having to escape certain characters, also make it harder to use your IDE's syntax checking and code completion features. This means that your template might require additional testing. Because

of these limitations, declaring functions inline is best suited for very simple code that does not change frequently.

To create a .zip file from inline code for Node.js and Python runtimes, set the following properties in your template's `AWS::Lambda::Function` resource:

- `PackageType` - Set to `Zip`
- `Code` - Enter your function code in the `ZipFile` field
- `Runtime` - Set to your chosen runtime

The .zip file that CloudFormation generates cannot exceed 4MB. To learn more about deploying functions using .zip file in CloudFormation, see [AWS::Lambda::Function](#) in the *CloudFormation User Guide*.

Deploy Python Lambda functions with container images

There are three ways to build a container image for a Python Lambda function:

- [Using an AWS base image for Python](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include the [runtime interface client for Python](#) in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the [runtime interface client for Python](#) in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

Topics

- [AWS base images for Python](#)
- [Using an AWS base image for Python](#)
- [Using an alternative base image with the runtime interface client](#)

AWS base images for Python

AWS provides the following base images for Python:

Tags	Runtime	Operating system	Dockerfile	Deprecation
3.14	Python 3.14	Amazon Linux 2023	Dockerfile for Python 3.14 on GitHub	Jun 30, 2029
3.13	Python 3.13	Amazon Linux 2023	Dockerfile for Python 3.13 on GitHub	Jun 30, 2029
3.12	Python 3.12	Amazon Linux 2023	Dockerfile for Python 3.12 on GitHub	Oct 31, 2028
3.11	Python 3.11	Amazon Linux 2	Dockerfile for Python 3.11 on GitHub	Jun 30, 2027
3.10	Python 3.10	Amazon Linux 2	Dockerfile for Python 3.10 on GitHub	Oct 31, 2026

Amazon ECR repository: gallery.ecr.aws/lambda/python

Python 3.12 and later base images are based on the [Amazon Linux 2023 minimal container image](#). The Python 3.8-3.11 base images are based on the Amazon Linux 2 image. AL2023-based images provide several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as `glibc`.

AL2023-based images use `microdnf` (symlinked as `dnf`) as the package manager instead of `yum`, which is the default package manager in Amazon Linux 2. `microdnf` is a standalone implementation of `dnf`. For a list of packages that are included in AL2023-based images, refer to the **Minimal Container** columns in [Comparing packages installed on Amazon Linux 2023 Container Images](#). For more information about the differences between AL2023 and Amazon Linux 2, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

Note

To run AL2023-based images locally, including with AWS Serverless Application Model (AWS SAM), you must use Docker version 20.10.10 or later.

Dependency search path in the base images

When you use an `import` statement in your code, the Python runtime searches the directories in its search path until it finds the module or package. By default, the runtime searches the `{LAMBDA_TASK_ROOT}` directory first. If you include a version of a runtime-included library in your image, your version will take precedence over the version that's included in the runtime.

Other steps in the search path depend on which version of the Lambda base image for Python you're using:

- **Python 3.11 and later:** Runtime-included libraries and pip-installed libraries are installed in the `/var/lang/lib/python3.11/site-packages` directory. This directory has precedence over `/var/runtime` in the search path. You can override the SDK by using pip to install a newer version. You can use pip to verify that the runtime-included SDK and its dependencies are compatible with any packages that you install.
- **Python 3.8-3.10:** Runtime-included libraries are installed in the `/var/runtime` directory. Pip-installed libraries are installed in the `/var/lang/lib/python3.x/site-packages` directory. The `/var/runtime` directory has precedence over `/var/lang/lib/python3.x/site-packages` in the search path.

You can see the full search path for your Lambda function by adding the following code snippet.

```
import sys

search_path = sys.path
print(search_path)
```

Using an AWS base image for Python

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Python

Creating an image from a base image

To create a container image from an AWS base image for Python

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new file called `lambda_function.py`. You can add the following sample function code to the file for testing, or use your own.

Example Python function

```
import sys
def handler(event, context):
    return 'Hello from AWS Lambda using Python' + sys.version + '!'
```

3. Create a new file called `requirements.txt`. If you're using the sample function code from the previous step, you can leave the file empty because there are no dependencies. Otherwise, list each required library. For example, here's what your `requirements.txt` should look like if your function uses the AWS SDK for Python (Boto3):

Example requirements.txt

```
boto3
```

4. Create a new Dockerfile with the following configuration:
 - Set the FROM property to the [URI of the base image](#).
 - Use the COPY command to copy the function code and runtime dependencies to `{LAMBDA_TASK_ROOT}`, a [Lambda-defined environment variable](#).
 - Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/python:3.12

# Copy requirements.txt
COPY requirements.txt ${LAMBDA_TASK_ROOT}

# Install the specified packages
RUN pip install -r requirements.txt

# Copy function code
COPY lambda_function.py ${LAMBDA_TASK_ROOT}

# Set the CMD to your handler (could also be done as a parameter override outside
  of the Dockerfile)
CMD [ "lambda_function.handler" ]
```

5. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

1. Start the Docker image with the **docker run** command. In this example, `docker-image` is the image name and `test` is the tag.

```
docker run --platform linux/amd64 -p 9000:8080 docker-image:test
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

2. From a new terminal window, post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType "application/json"
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \  
  --function-name hello-world \  
  --package-type Image \  
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{  
  "ExecutedVersion": "$LATEST",  
  "StatusCode": 200  
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Using an alternative base image with the runtime interface client

If you use an [OS-only base image](#) or an alternative base image, you must include the runtime interface client in your image. The runtime interface client extends the [Runtime API](#), which manages the interaction between Lambda and your function code.

Install the the [runtime interface client for Python](#) using the pip package manager:

```
pip install awslambdarc
```

You can also download the [Python runtime interface client](#) from GitHub.

The following example demonstrates how to build a container image for Python using a non-AWS base image. The example Dockerfile uses an official Python base image. The Dockerfile includes the runtime interface client for Python.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)

- The Docker [buildx plugin](#).
- Python

Creating an image from an alternative base image

To create a container image from a non-AWS base image

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new file called `lambda_function.py`. You can add the following sample function code to the file for testing, or use your own.

Example Python function

```
import sys
def handler(event, context):
    return 'Hello from AWS Lambda using Python' + sys.version + '!'
```

3. Create a new file called `requirements.txt`. If you're using the sample function code from the previous step, you can leave the file empty because there are no dependencies. Otherwise, list each required library. For example, here's what your `requirements.txt` should look like if your function uses the AWS SDK for Python (Boto3):

Example requirements.txt

```
boto3
```

4. Create a new Dockerfile. The following Dockerfile uses an official Python base image instead of an [AWS base image](#). The Dockerfile includes the [runtime interface client](#), which makes the image compatible with Lambda. The following example Dockerfile uses a [multi-stage build](#).
 - Set the FROM property to the base image.
 - Set the ENTRYPOINT to the module that you want the Docker container to run when it starts. In this case, the module is the runtime interface client.
 - Set the CMD to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
# Define custom function directory
ARG FUNCTION_DIR="/function"

FROM python:3.12 AS build-image

# Include global arg in this stage of the build
ARG FUNCTION_DIR

# Copy function code
RUN mkdir -p ${FUNCTION_DIR}
COPY . ${FUNCTION_DIR}

# Install the function's dependencies
RUN pip install \
    --target ${FUNCTION_DIR} \
        awslambdarc

# Use a slim version of the base Python image to reduce the final image size
FROM python:3.12-slim

# Include global arg in this stage of the build
ARG FUNCTION_DIR
# Set working directory to function root directory
WORKDIR ${FUNCTION_DIR}

# Copy in the built dependencies
COPY --from=build-image ${FUNCTION_DIR} ${FUNCTION_DIR}

# Set runtime interface client as default command for the container runtime
ENTRYPOINT [ "/usr/local/bin/python", "-m", "awslambdarc" ]
# Pass the name of the function handler as an argument to the runtime
CMD [ "lambda_function.handler" ]
```

5. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test the image. You can [build the emulator into your image](#) or use the following procedure to install it on your local machine.

To install and run the runtime interface emulator on your local machine

1. From your project directory, run the following command to download the runtime interface emulator (x86-64 architecture) from GitHub and install it on your local machine.

Linux/macOS

```
mkdir -p ~/.aws-lambda-rie && \
  curl -Lo ~/.aws-lambda-rie/aws-lambda-rie https://github.com/aws/aws-lambda-
runtime-interface-emulator/releases/latest/download/aws-lambda-rie && \
  chmod +x ~/.aws-lambda-rie/aws-lambda-rie
```

To install the arm64 emulator, replace the GitHub repository URL in the previous command with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/
download/aws-lambda-rie-arm64
```

PowerShell

```
$dirPath = "$HOME\.aws-lambda-rie"
if (-not (Test-Path $dirPath)) {
    New-Item -Path $dirPath -ItemType Directory
}

$downloadLink = "https://github.com/aws/aws-lambda-runtime-interface-emulator/
releases/latest/download/aws-lambda-rie"
$destinationPath = "$HOME\.aws-lambda-rie\aws-lambda-rie"
Invoke-WebRequest -Uri $downloadLink -OutFile $destinationPath
```

To install the arm64 emulator, replace the `$downloadLink` with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/
download/aws-lambda-rie-arm64
```

2. Start the Docker image with the **docker run** command. Note the following:

- `docker-image` is the image name and `test` is the tag.
- `/usr/local/bin/python -m awslambdarc lambda_function.handler` is the ENTRYPOINT followed by the CMD from your Dockerfile.

Linux/macOS

```
docker run --platform linux/amd64 -d -v ~/.aws-lambda-rie:/aws-lambda -p
9000:8080 \
    --entrypoint /aws-lambda/aws-lambda-rie \
    docker-image:test \
    /usr/local/bin/python -m awslambdarc lambda_function.handler
```

PowerShell

```
docker run --platform linux/amd64 -d -v "$HOME\.aws-lambda-rie:/aws-lambda" -p
9000:8080 `
--entrypoint /aws-lambda/aws-lambda-rie `
docker-image:test `
/usr/local/bin/python -m awslambdarc lambda_function.handler
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

 **Note**

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

3. Post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType  
"application/json"
```

4. Get the container ID.

```
docker ps
```

5. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
```

```

    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-
world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-
world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}

```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-
world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.

7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

 **Note**

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

For an example of how to create a Python image from an Alpine base image, see [Container image support for Lambda](#) on the AWS Blog.

Working with layers for Python Lambda functions

Use [Lambda layers](#) to package code and dependencies that you want to reuse across multiple functions. Layers usually contain library dependencies, a [custom runtime](#), or configuration files. Creating a layer involves three general steps:

1. Package your layer content. This means creating a .zip file archive that contains the dependencies you want to use in your functions.
2. Create the layer in Lambda.
3. Add the layer to your functions.

Topics

- [Package your layer content](#)
- [Create the layer in Lambda](#)
- [Add the layer to your function](#)
- [Sample app](#)

Package your layer content

To create a layer, bundle your packages into a .zip file archive that meets the following requirements:

- Build the layer using the same Python version that you plan to use for the Lambda function. For example, if you build your layer using Python 3.14, use the Python 3.14 runtime for your function.
- Your .zip file must include a python directory at the root level.
- The packages in your layer must be compatible with Linux. Lambda functions run on Amazon Linux.

You can create layers that contain either third-party Python libraries installed with pip (such as requests or pandas) or your own Python modules and packages.

Third-party dependencies

To create a layer using pip packages

1. Choose one of the following methods to install pip packages into the required top-level directory (python/):

pip install

For pure Python packages (like requests or boto3):

```
pip install requests -t python/
```

Some Python packages, such as NumPy and Pandas, include compiled C components. If you're building a layer with these packages on macOS or Windows, you might need to use this command to install a Linux-compatible wheel:

```
pip install numpy --platform manylinux2014_x86_64 --only-binary=:all: -t python/
```

For more information about working with Python packages that contain compiled components, see [Creating .zip deployment packages with native libraries](#).

requirements.txt

Using a `requirements.txt` file helps you manage package versions and ensure consistent installations.

Example requirements.txt

```
requests==2.31.0  
boto3==1.37.34  
numpy==1.26.4
```

If your `requirements.txt` file includes only pure Python packages (like requests or boto3):

```
pip install -r requirements.txt -t python/
```

Some Python packages, such as NumPy and Pandas, include compiled C components. If you're building a layer with these packages on macOS or Windows, you might need to use this command to install a Linux-compatible wheel:

```
pip install -r requirements.txt --platform manylinux2014_x86_64 --only-binary=:all: -t python/
```

For more information about working with Python packages that contain compiled components, see [Creating .zip deployment packages with native libraries](#).

2. Zip the contents of the python directory.

Linux/macOS

```
zip -r layer.zip python/
```

PowerShell

```
Compress-Archive -Path .\python -DestinationPath .\layer.zip
```

The directory structure of your .zip file should look like this:

```
python/                # Required top-level directory
### requests/
### boto3/
### numpy/
### (dependencies of the other packages)
```

Note

If you use a Python virtual environment (venv) to install packages, your directory structure will be different (for example, `python/lib/python3.x/site-packages`). As long as your .zip file includes the python directory at the root level, Lambda can locate and import your packages.

Custom Python modules

To create a layer using your own code

1. Create the required top-level directory for your layer:

```
mkdir python
```

2. Create your Python modules in the python directory. The following example module validates orders by confirming that they contain the required information.

Example custom module: validator.py

```
import json

def validate_order(order_data):
    """Validates an order and returns formatted data."""
    required_fields = ['product_id', 'quantity']

    # Check required fields
    missing_fields = [field for field in required_fields if field not in
order_data]
    if missing_fields:
        raise ValueError(f"Missing required fields: {' '.join(missing_fields)}")

    # Validate quantity
    quantity = order_data['quantity']
    if not isinstance(quantity, int) or quantity < 1:
        raise ValueError("Quantity must be a positive integer")

    # Format and return the validated data
    return {
        'product_id': str(order_data['product_id']),
        'quantity': quantity,
        'shipping_priority': order_data.get('priority', 'standard')
    }

def format_response(status_code, body):
    """Formats the API response."""
    return {
        'statusCode': status_code,
        'body': json.dumps(body)
```

```
}
```

3. Zip the contents of the python directory.

Linux/macOS

```
zip -r layer.zip python/
```

PowerShell

```
Compress-Archive -Path .\python -DestinationPath .\layer.zip
```

The directory structure of your .zip file should look like this:

```
python/      # Required top-level directory  
### validator.py
```

4. In your function, import and use the modules as you would with any Python package. Example:

```
from validator import validate_order, format_response  
import json  
  
def lambda_handler(event, context):  
    try:  
        # Parse the order data from the event body  
        order_data = json.loads(event.get('body', '{}'))  
  
        # Validate and format the order  
        validated_order = validate_order(order_data)  
  
        return format_response(200, {  
            'message': 'Order validated successfully',  
            'order': validated_order  
        })  
    except ValueError as e:  
        return format_response(400, {  
            'error': str(e)  
        })  
    except Exception as e:  
        return format_response(500, {  
            'error': 'Internal server error'
```

```
})
```

You can use the following [test event](#) to invoke the function:

```
{
  "body": "{\"product_id\": \"ABC123\", \"quantity\": 2, \"priority\": \"express\"}"
}
```

Expected response:

```
{
  "statusCode": 200,
  "body": "{\"message\": \"Order validated successfully\", \"order\": {\"product_id\": \"ABC123\", \"quantity\": 2, \"shipping_priority\": \"express\"}}"
```

Create the layer in Lambda

You can publish your layer using either the AWS CLI or the Lambda console.

AWS CLI

Run the [publish-layer-version](#) AWS CLI command to create the Lambda layer:

```
aws lambda publish-layer-version --layer-name my-layer --zip-file fileb://layer.zip
--compatible-runtimes python3.14
```

The [compatible runtimes](#) parameter is optional. When specified, Lambda uses this parameter to filter layers in the Lambda console.

Console

To create a layer (console)

1. Open the [Layers page](#) of the Lambda console.
2. Choose **Create layer**.
3. Choose **Upload a .zip file**, and then upload the .zip archive that you created earlier.

4. (Optional) For **Compatible runtimes**, choose the Python runtime that corresponds to the Python version you used to build your layer.
5. Choose **Create**.

Add the layer to your function

AWS CLI

To attach the layer to your function, run the [update-function-configuration](#) AWS CLI command. For the `--layers` parameter, use the layer ARN. The ARN must specify the version (for example, `arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1`). For more information, see [Layers and layer versions](#).

```
aws lambda update-function-configuration --function-name my-function --cli-binary-format raw-in-base64-out --layers "arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1"
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

Console

To add a layer to a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function.
3. Scroll down to the **Layers** section, and then choose **Add a layer**.
4. Under **Choose a layer**, select **Custom layers**, and then choose your layer.

Note

If you didn't add a [compatible runtime](#) when you created the layer, your layer won't be listed here. You can specify the layer ARN instead.

5. Choose **Add**.

Sample app

For more examples of how to use Lambda layers, see the [layer-python](#) sample application in the AWS Lambda Developer Guide GitHub repository. This application includes two layers that contain Python libraries. After creating the layers, you can deploy and invoke the corresponding functions to confirm that the layers work as expected.

Using the Lambda context object to retrieve Python function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides methods and properties that provide information about the invocation, function, and execution environment. For more information on how the context object is passed to the function handler, see [Define Lambda function handler in Python](#).

Context methods

- `get_remaining_time_in_millis` – Returns the number of milliseconds left before the execution times out.

Context properties

- `function_name` – The name of the Lambda function.
- `function_version` – The [version](#) of the function.
- `invoked_function_arn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `memory_limit_in_mb` – The amount of memory that's allocated for the function.
- `aws_request_id` – The identifier of the invocation request.
- `log_group_name` – The log group for the function.
- `log_stream_name` – The log stream for the function instance.
- `identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
 - `cognito_identity_id` – The authenticated Amazon Cognito identity.
 - `cognito_identity_pool_id` – The Amazon Cognito identity pool that authorized the invocation.
- `client_context` – (mobile apps) Client context that's provided to Lambda by the client application.
 - `client.installation_id`
 - `client.app_title`
 - `client.app_version_name`
 - `client.app_version_code`

- `client.app_package_name`
- `custom` – A dict of custom values set by the mobile client application.
- `env` – A dict of environment information provided by the AWS SDK.

Powertools for Lambda (Python) provides an interface definition for the Lambda context object. You can use the interface definition for type hints, or to further inspect the structure of the Lambda context object. For the interface definition, see [lambda_context.py](#) in the *powertools-lambda-python* repository on GitHub.

The following example shows a handler function that logs context information.

Example handler.py

```
import time

def lambda_handler(event, context):
    print("Lambda function ARN:", context.invoked_function_arn)
    print("CloudWatch log stream name:", context.log_stream_name)
    print("CloudWatch log group name:", context.log_group_name)
    print("Lambda Request ID:", context.aws_request_id)
    print("Lambda function memory limits in MB:", context.memory_limit_in_mb)
    # We have added a 1 second delay so you can see the time remaining in
    get_remaining_time_in_millis.
    time.sleep(1)
    print("Lambda time remaining in MS:", context.get_remaining_time_in_millis())
```

In addition to the options listed above, you can also use the AWS X-Ray SDK for [Instrumenting Python code in AWS Lambda](#) to identify critical code paths, trace their performance and capture the data for analysis.

Log and monitor Python Lambda functions

AWS Lambda automatically monitors Lambda functions and sends log entries to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation and other output from your function's code to the log stream. For more information about CloudWatch Logs, see [Sending Lambda function logs to CloudWatch Logs](#).

To output logs from your function code, you can use the built-in [logging](#) module. For more detailed entries, you can use any logging library that writes to `stdout` or `stderr`.

Printing to the log

To send basic output to the logs, you can use a `print` method in your function. The following example logs the values of the CloudWatch Logs log group and stream, and the event object.

Note that if your function outputs logs using Python `print` statements, Lambda can only send log outputs to CloudWatch Logs in plain text format. To capture logs in structured JSON, you need to use a supported logging library. See [the section called “Using Lambda advanced logging controls with Python”](#) for more information.

Example `lambda_function.py`

```
import os
def lambda_handler(event, context):
    print('## ENVIRONMENT VARIABLES')
    print(os.environ['AWS_LAMBDA_LOG_GROUP_NAME'])
    print(os.environ['AWS_LAMBDA_LOG_STREAM_NAME'])
    print('## EVENT')
    print(event)
```

Example log output

```
START RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95 Version: $LATEST
## ENVIRONMENT VARIABLES
/aws/lambda/my-function
2025/08/31/[$LATEST]3893xmpl7fac4485b47bb75b671a283c
## EVENT
{'key': 'value'}
```

```
END RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95
REPORT RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95  Duration: 15.74 ms  Billed
  Duration: 147 ms Memory Size: 128 MB Max Memory Used: 56 MB  Init Duration: 130.49 ms
XRAY TraceId: 1-5e34a614-10bdxmplf1fb44f07bc535a1  SegmentId: 07f5xmpl2d1f6f85
  Sampled: true
```

The Python runtime logs the START, END, and REPORT lines for each invocation. The REPORT line includes the following data:

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

Using a logging library

For more detailed logs, use the [logging](#) module in the standard library, or any third party logging library that writes to `stdout` or `stderr`.

For supported Python runtimes, you can choose whether logs created using the standard logging module are captured in plain text or JSON. To learn more, see [the section called “Using Lambda advanced logging controls with Python”](#).

Currently, the default log format for all Python runtimes is plain text. The following example shows how log outputs created using the standard logging module are captured in plain text in CloudWatch Logs.

```
import os
import logging
logger = logging.getLogger()
logger.setLevel("INFO")

def lambda_handler(event, context):
    logger.info('## ENVIRONMENT VARIABLES')
    logger.info(os.environ['AWS_LAMBDA_LOG_GROUP_NAME'])
    logger.info(os.environ['AWS_LAMBDA_LOG_STREAM_NAME'])
    logger.info('## EVENT')
    logger.info(event)
```

The output from `logger` includes the log level, timestamp, and request ID.

```

Note

When your function's log format is set to plain text, the default log-level setting for Python runtimes is `WARN`. This means that Lambda only sends log outputs of level `WARN` and lower to CloudWatch Logs. To change the default log level, use the Python logging `setLevel()` method as shown in this example code. If you set your function's log format to JSON, we recommend that you configure your function's log level using Lambda Advanced Logging Controls and not by setting the log level in code. To learn more, see [the section called “Using log-level filtering with Python”](#)

Using Lambda advanced logging controls with Python

To give you more control over how your functions' logs are captured, processed, and consumed, you can configure the following logging options for supported Lambda Python runtimes:

- **Log format** - select between plain text and structured JSON format for your function's logs
- **Log level** - for logs in JSON format, choose the detail level of the logs Lambda sends to Amazon CloudWatch, such as ERROR, DEBUG, or INFO
- **Log group** - choose the CloudWatch log group your function sends logs to

For more information about these logging options, and instructions on how to configure your function to use them, see [the section called "Configuring advanced logging controls for Lambda functions"](#).

To learn more about using the log format and log level options with your Python Lambda functions, see the guidance in the following sections.

Using structured JSON logs with Python

If you select JSON for your function's log format, Lambda will send logs output by the Python standard logging library to CloudWatch as structured JSON. Each JSON log object contains at least four key value pairs with the following keys:

- "timestamp" - the time the log message was generated
- "level" - the log level assigned to the message
- "message" - the contents of the log message
- "requestId" - the unique request ID for the function invocation

The Python logging library can also add extra key value pairs such as "logger" to this JSON object.

The examples in the following sections show how log outputs generated using the Python logging library are captured in CloudWatch Logs when you configure your function's log format as JSON.

Note that if you use the `print` method to produce basic log outputs as described in [the section called "Printing to the log"](#), Lambda will capture these outputs as plain text, even if you configure your function's logging format as JSON.

Standard JSON log outputs using Python logging library

The following example code snippet and log output show how standard log outputs generated using the Python logging library are captured in CloudWatch Logs when your function's log format is set to JSON.

Example Python logging code

```
import logging
logger = logging.getLogger()

def lambda_handler(event, context):
    logger.info("Inside the handler function")
```

Example JSON log record

```
{
  "timestamp": "2025-10-27T19:17:45.586Z",
  "level": "INFO",
  "message": "Inside the handler function",
  "logger": "root",
  "requestId": "79b4f56e-95b1-4643-9700-2807f4e68189"
}
```

Logging extra parameters in JSON

When your function's log format is set to JSON, you can also log additional parameters with the standard Python logging library by using the `extra` keyword to pass a Python dictionary to the log output.

Example Python logging code

```
import logging

def lambda_handler(event, context):
    logging.info(
        "extra parameters example",
        extra={"a": "b", "b": [3]},
    )
```

Example JSON log record

```
{
  "timestamp": "2025-11-02T15:26:28Z",
  "level": "INFO",
  "message": "extra parameters example",
  "logger": "root",
  "requestId": "3dbd5759-65f6-45f8-8d7d-5bdc79a3bd01",
  "a": "b",
  "b": [
    3
  ]
}
```

Logging exceptions in JSON

The following code snippet shows how Python exceptions are captured in your function's log output when you configure the log format as JSON. Note that log outputs generated using `logging.exception` are assigned the log level `ERROR`.

Example Python logging code

```
import logging

def lambda_handler(event, context):
    try:
        raise Exception("exception")
    except:
        logging.exception("msg")
```

Example JSON log record

```
{
  "timestamp": "2025-11-02T16:18:57Z",
  "level": "ERROR",
  "message": "msg",
  "logger": "root",
  "stackTrace": [
    "  File \"./var/task/lambda_function.py\", line 15, in lambda_handler\n    raise\nException(\"exception\")\n"
  ],
}
```

```
"errorType": "Exception",
"errorMessage": "exception",
"requestId": "3f9d155c-0f09-46b7-bdf1-e91dab220855",
"location": "/var/task/lambda_function.py:lambda_handler:17"
}
```

JSON structured logs with other logging tools

If your code already uses another logging library, such as Powertools for AWS Lambda, to produce JSON structured logs, you don't need to make any changes. AWS Lambda doesn't double-encode any logs that are already JSON encoded. Even if you configure your function to use the JSON log format, your logging outputs appear in CloudWatch in the JSON structure you define.

The following example shows how log outputs generated using the Powertools for AWS Lambda package are captured in CloudWatch Logs. The format of this log output is the same whether your function's logging configuration is set to JSON or TEXT. For more information about using Powertools for AWS Lambda, see [the section called "Using Powertools for AWS Lambda \(Python\) and AWS SAM for structured logging"](#) and [the section called "Using Powertools for AWS Lambda \(Python\) and AWS CDK for structured logging"](#)

Example Python logging code snippet (using Powertools for AWS Lambda)

```
from aws_lambda_powertools import Logger

logger = Logger()

def lambda_handler(event, context):
    logger.info("Inside the handler function")
```

Example JSON log record (using Powertools for AWS Lambda)

```
{
  "level": "INFO",
  "location": "lambda_handler:7",
  "message": "Inside the handler function",
  "timestamp": "2025-10-31 22:38:21,010+0000",
  "service": "service_undefined",
  "xray_trace_id": "1-654181dc-65c15d6b0fecbdd1531ecb30"
}
```

Using log-level filtering with Python

By configuring log-level filtering, you can choose to send only logs of a certain logging level or lower to CloudWatch Logs. To learn how to configure log-level filtering for your function, see [the section called “Log-level filtering”](#).

For AWS Lambda to filter your application logs according to their log level, your function must use JSON formatted logs. You can achieve this in two ways:

- Create log outputs using the standard Python logging library and configure your function to use JSON log formatting. AWS Lambda then filters your log outputs using the “level” key value pair in the JSON object described in [the section called “Using structured JSON logs with Python”](#). To learn how to configure your function’s log format, see [the section called “Configuring advanced logging controls for Lambda functions”](#).
- Use another logging library or method to create JSON structured logs in your code that include a “level” key value pair defining the level of the log output. For example, you can use Powertools for AWS Lambda to generate JSON structured log outputs from your code.

You can also use a print statement to output a JSON object containing a log level identifier. The following print statement produces a JSON formatted output where the log level is set to INFO. AWS Lambda will send the JSON object to CloudWatch Logs if your function’s logging level is set to INFO, DEBUG, or TRACE.

```
print({'msg':"My log message", "level":"info"})
```

For Lambda to filter your function's logs, you must also include a "timestamp" key value pair in your JSON log output. The time must be specified in valid [RFC 3339](#) timestamp format. If you don't supply a valid timestamp, Lambda will assign the log the level INFO and add a timestamp for you.

Viewing logs in Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs with AWS CLI

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElk0iA4N2QwNDRI0C1mMTU0LTExZTgt0GNkYS0yOTc0YzVlNGZiMjEgVmVyc2lva... ",
  "ExecutedVersion": "$LATEST"
```

```
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \  
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --  
decode
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST  
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-  
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",  
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8  
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed  
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB
```

The `base64` utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more

information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"//g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
{
  "events": [
    {
      "timestamp": 1559763003171,
      "message": "START RequestId: 4ce9340a-b765-490f-ad8a-02ab3415e2bf Version:

}

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Using other logging tools and libraries

[Powertools for AWS Lambda \(Python\)](#) is a developer toolkit to implement Serverless best practices and increase developer velocity. The [Logger utility](#) provides a Lambda optimized logger which includes additional information about function context across all your functions with output structured as JSON. Use this utility to do the following:

- Capture key fields from the Lambda context, cold start and structures logging output as JSON

- Log Lambda invocation events when instructed (disabled by default)
- Print all the logs only for a percentage of invocations via log sampling (disabled by default)
- Append additional keys to structured log at any point in time
- Use a custom log formatter (Bring Your Own Formatter) to output logs in a structure compatible with your organization's Logging RFC

Using Powertools for AWS Lambda (Python) and AWS SAM for structured logging

Follow the steps below to download, build, and deploy a sample Hello World Python application with integrated [Powertools for Python](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- Python 3.9
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World Python template.

```
sam init --app-template hello-world-powertools-python --name sam-app --package-type Zip --runtime python3.9 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query  
'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name sam-app
```

The log output looks like this:

```
2025/02/03/[$LATEST]ea9a64ec87294bf6bbc9026c05a01e04

```

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Managing log retention

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or configure a retention period after which CloudWatch automatically deletes the logs. To set up log retention, add the following to your AWS SAM template:

Resources:**HelloWorldFunction:**

Type: `AWS::Serverless::Function`

Properties:

Omitting other properties

LogGroup:

Type: `AWS::Logs::LogGroup`

Properties:

LogGroupName: `!Sub "/aws/lambda/${HelloWorldFunction}"`

RetentionInDays: `7`

Using Powertools for AWS Lambda (Python) and AWS CDK for structured logging

Follow the steps below to download, build, and deploy a sample Hello World Python application with integrated [Powertools for AWS Lambda \(Python\)](#) modules using the AWS CDK. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Python 3.9
- [AWS CLI version 2](#)
- [AWS CDK version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS CDK application

1. Create a project directory for your new application.

```
mkdir hello-world
```

```
cd hello-world
```

2. Initialize the app.

```
cdk init app --language python
```

3. Install the Python dependencies.

```
pip install -r requirements.txt
```

4. Create a directory **lambda_function** under the root folder.

```
mkdir lambda_function  
cd lambda_function
```

5. Create a file **app.py** and add the following code to the file. This is the code for the Lambda function.

```
from aws_lambda_powertools.event_handler import APIGatewayRestResolver  
from aws_lambda_powertools.utilities.typing import LambdaContext  
from aws_lambda_powertools.logging import correlation_paths  
from aws_lambda_powertools import Logger  
from aws_lambda_powertools import Tracer  
from aws_lambda_powertools import Metrics  
from aws_lambda_powertools.metrics import MetricUnit  
  
app = APIGatewayRestResolver()  
tracer = Tracer()  
logger = Logger()  
metrics = Metrics(namespace="PowertoolsSample")  
  
@app.get("/hello")  
@tracer.capture_method  
def hello():  
    # adding custom metrics  
    # See: https://docs.aws.amazon.com/powertools/python/latest/latest/core/metrics/  
    metrics.add_metric(name="HelloWorldInvocations", unit=MetricUnit.Count,  
                      value=1)  
  
    # structured log  
    # See: https://docs.aws.amazon.com/powertools/python/latest/latest/core/logger/
```

```

    logger.info("Hello world API - HTTP 200")
    return {"message": "hello world"}

# Enrich logging with contextual information from Lambda
@logger.inject_lambda_context(correlation_id_path=correlation_paths.API_GATEWAY_REST)
# Adding tracer
# See: https://docs.aws.amazon.com/powertools/python/latest/latest/core/tracer/
@tracer.capture_lambda_handler
# ensures metrics are flushed upon request completion/failure and capturing
ColdStart metric
@metrics.log_metrics(capture_cold_start_metric=True)
def lambda_handler(event: dict, context: LambdaContext) -> dict:
    return app.resolve(event, context)

```

6. Open the **hello_world** directory. You should see a file called **hello_world_stack.py**.

```

cd ..
cd hello_world

```

7. Open **hello_world_stack.py** and add the following code to the file. This contains the [Lambda Constructor](#), which creates the Lambda function, configures environment variables for Powertools and sets log retention to one week, and the [ApiGatewayv1 Constructor](#), which creates the REST API.

```

from aws_cdk import (
    Stack,
    aws_apigateway as apigwv1,
    aws_lambda as lambda_,
    CfnOutput,
    Duration
)
from constructs import Construct

class HelloWorldStack(Stack):

    def __init__(self, scope: Construct, construct_id: str, **kwargs) -> None:
        super().__init__(scope, construct_id, **kwargs)

        # Powertools Lambda Layer
        powertools_layer = lambda_.LayerVersion.from_layer_version_arn(
            self,
            id="lambda-powertools",
            # Using AWS Lambda Powertools via Lambda Layer

```

```

        # This imports the Powertools layer which provides observability
        features for Lambda functions
        # For available versions, see: https://docs.aws.amazon.com/powertools/
python/latest/#lambda-layer
    )

    function = lambda_.Function(self,
        'sample-app-lambda',
        runtime=lambda_.Runtime.PYTHON_3_9,
        layers=[powertools_layer],
        code = lambda_.Code.from_asset("./lambda_function/"),
        handler="app.lambda_handler",
        memory_size=128,
        timeout=Duration.seconds(3),
        architecture=lambda_.Architecture.X86_64,
        environment={
            "POWERTOOLS_SERVICE_NAME": "PowertoolsHelloWorld",
            "POWERTOOLS_METRICS_NAMESPACE": "PowertoolsSample",
            "LOG_LEVEL": "INFO"
        }
    )

    apigw = apigwv1.RestApi(self, "PowertoolsAPI",
    deploy_options=apigwv1.StageOptions(stage_name="dev"))

    hello_api = apigw.root.add_resource("hello")
    hello_api.add_method("GET", apigwv1.LambdaIntegration(function,
    proxy=True))

    CfnOutput(self, "apiUrl", value=f"{apigw.url}hello")

```

8. Deploy your application.

```

cd ..
cdk deploy

```

9. Get the URL of the deployed application:

```

aws cloudformation describe-stacks --stack-name HelloWorldStack --query
'Stacks[0].Outputs[?OutputKey==`apiUrl`].OutputValue' --output text

```

10. Invoke the API endpoint:

```
curl GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

11. To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name HelloWorldStack
```

The log output looks like this:

```

AWS Lambda function testing in Python

Note

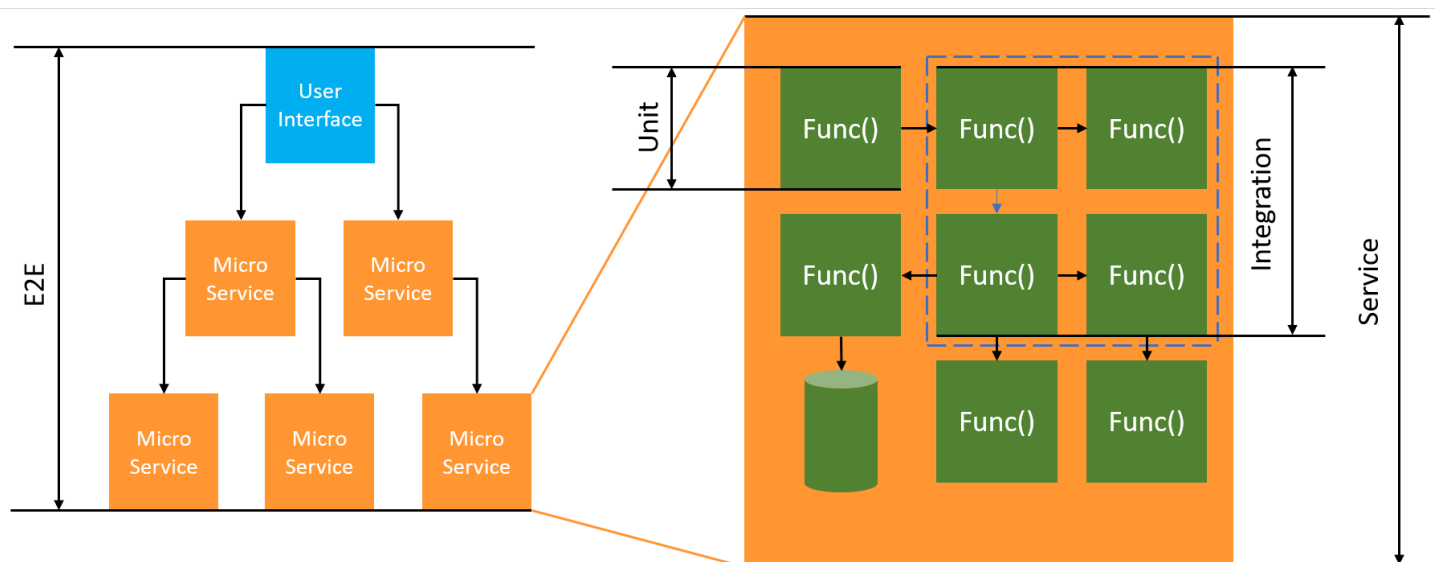

See the [Testing functions](#) chapter for a complete introduction to techniques and best practices for testing serverless solutions.

Testing serverless functions uses traditional test types and techniques, but you must also consider testing serverless applications as a whole. Cloud-based tests will provide the **most accurate** measure of quality of both your functions and serverless applications.

A serverless application architecture includes managed services that provide critical application functionality through API calls. For this reason, your development cycle should include automated tests that verify functionality when your function and services interact.

If you do not create cloud-based tests, you could encounter issues due to differences between your local environment and the deployed environment. Your continuous integration process should run tests against a suite of resources provisioned in the cloud before promoting your code to the next deployment environment, such as QA, Staging, or Production.

Continue reading this short guide to learn about testing strategies for serverless applications, or visit the [Serverless Test Samples repository](#) to dive in with practical examples, specific to your chosen language and runtime.

For serverless testing, you will still write *unit*, *integration* and *end-to-end* tests.

- **Unit tests** - Tests that run against an isolated block of code. For example, verifying the business logic to calculate the delivery charge given a particular item and destination.
- **Integration tests** - Tests involving two or more components or services that interact, typically in a cloud environment. For example, verifying a function processes events from a queue.
- **End-to-end tests** - Tests that verify behavior across an entire application. For example, ensuring infrastructure is set up correctly and that events flow between services as expected to record a customer's order.

Testing your serverless applications

You will generally use a mix of approaches to test your serverless application code, including testing in the cloud, testing with mocks, and occasionally testing with emulators.

Testing in the cloud

Testing in the cloud is valuable for all phases of testing, including unit tests, integration tests, and end-to-end tests. You run tests against code deployed in the cloud and interacting with cloud-based services. This approach provides the **most accurate** measure of quality of your code.

A convenient way to debug your Lambda function in the cloud is through the console with a test event. A *test event* is a JSON input to your function. If your function does not require input, the event can be an empty JSON document (`{}`). The console provides sample events for a variety of service integrations. After creating an event in the console, you can share it with your team to make testing easier and consistent.

Note

[Testing a function in the console](#) is a quick way to get started, but automating your test cycles ensures application quality and development speed.

Testing tools

Tools and techniques exist to accelerate development feedback loops. For example, [AWS SAM Accelerate](#) and [AWS CDK watch mode](#) both decrease the time required to update cloud environments.

[Moto](#) is a Python library for mocking AWS services and resources, so that you can test your functions with little or no modification using decorators to intercept and simulate responses.

The validation feature of the [Powertools for AWS Lambda \(Python\)](#) provides decorators so you can validate input events and output responses from your Python functions.

For more information, read the blog post [Unit Testing Lambda with Python and Mock AWS Services](#).

To reduce the latency involved with cloud deployment iterations, see [AWS Serverless Application Model \(AWS SAM\) Accelerate](#), [AWS Cloud Development Kit \(AWS CDK\) watch mode](#). These tools monitor your infrastructure and code for changes. They react to these changes by creating and deploying incremental updates automatically into your cloud environment.

Examples that use these tools are available in the [Python Test Samples](#) code repository.

Instrumenting Python code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of three SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for Python](#) – An SDK for generating and sending trace data to X-Ray.
- [Powertools for AWS Lambda \(Python\)](#) – A developer toolkit to implement Serverless best practices and increase developer velocity.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

Using Powertools for AWS Lambda (Python) and AWS SAM for tracing

Follow the steps below to download, build, and deploy a sample Hello World Python application with integrated [Powertools for AWS Lambda \(Python\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Python 3.11
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World Python template.

```
sam init --app-template hello-world-powertools-python --name sam-app --package-type Zip --runtime python3.11 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query
  'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl -X GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

```
New XRay Service Graph
  Start time: 2023-02-03 14:59:50+00:00

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

Using Powertools for AWS Lambda (Python) and the AWS CDK for tracing

Follow the steps below to download, build, and deploy a sample Hello World Python application with integrated [Powertools for AWS Lambda \(Python\)](#) modules using the AWS CDK. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics

using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Python 3.11
- [AWS CLI version 2](#)
- [AWS CDK version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS CDK application

1. Create a project directory for your new application.

```
mkdir hello-world
cd hello-world
```

2. Initialize the app.

```
cdk init app --language python
```

3. Install the Python dependencies.

```
pip install -r requirements.txt
```

4. Create a directory **lambda_function** under the root folder.

```
mkdir lambda_function
cd lambda_function
```

5. Create a file **app.py** and add the following code to the file. This is the code for the Lambda function.

```
from aws_lambda_powertools.event_handler import APIGatewayRestResolver
from aws_lambda_powertools.utilities.typing import LambdaContext
from aws_lambda_powertools.logging import correlation_paths
from aws_lambda_powertools import Logger
```

```

from aws_lambda_powertools import Tracer
from aws_lambda_powertools import Metrics
from aws_lambda_powertools.metrics import MetricUnit

app = APIGatewayRestResolver()
tracer = Tracer()
logger = Logger()
metrics = Metrics(namespace="PowertoolsSample")

@app.get("/hello")
@tracer.capture_method
def hello():
    # adding custom metrics
    # See: https://docs.powertools.aws.dev/lambda-python/latest/core/metrics/
    metrics.add_metric(name="HelloWorldInvocations", unit=MetricUnit.Count,
value=1)

    # structured log
    # See: https://docs.powertools.aws.dev/lambda-python/latest/core/logger/
    logger.info("Hello world API - HTTP 200")
    return {"message": "hello world"}

# Enrich logging with contextual information from Lambda
@logger.inject_lambda_context(correlation_id_path=correlation_paths.API_GATEWAY_REST)
# Adding tracer
# See: https://docs.powertools.aws.dev/lambda-python/latest/core/tracer/
@tracer.capture_lambda_handler
# ensures metrics are flushed upon request completion/failure and capturing
ColdStart metric
@metrics.log_metrics(capture_cold_start_metric=True)
def lambda_handler(event: dict, context: LambdaContext) -> dict:
    return app.resolve(event, context)

```

6. Open the **hello_world** directory. You should see a file called **hello_world_stack.py**.

```

cd ..
cd hello_world

```

7. Open **hello_world_stack.py** and add the following code to the file. This contains the [Lambda Constructor](#), which creates the Lambda function, configures environment variables for Powertools and sets log retention to one week, and the [ApiGatewayv1 Constructor](#), which creates the REST API.

```

from aws_cdk import (
    Stack,
    aws_apigateway as apigwv1,
    aws_lambda as lambda_,
    CfnOutput,
    Duration
)
from constructs import Construct

class HelloWorldStack(Stack):

    def __init__(self, scope: Construct, construct_id: str, **kwargs) -> None:
        super().__init__(scope, construct_id, **kwargs)

        # Powertools Lambda Layer
        powertools_layer = lambda_.LayerVersion.from_layer_version_arn(
            self,
            id="lambda-powertools",
            # At the moment we wrote this example, the aws_lambda_python_alpha CDK
            # constructor is in Alpha, so we use layer to make the example simpler
            # See https://docs.aws.amazon.com/cdk/api/v2/python/
            # Check all Powertools layers versions here: https://
            layer_version_arn=f"arn:aws:lambda:
{self.region}:017000801446:layer:AWSLambdaPowertoolsPythonV2:21"
        )

        function = lambda_.Function(self,
            'sample-app-lambda',
            runtime=lambda_.Runtime.PYTHON_3_11,
            layers=[powertools_layer],
            code = lambda_.Code.from_asset("./lambda_function/"),
            handler="app.lambda_handler",
            memory_size=128,
            timeout=Duration.seconds(3),
            architecture=lambda_.Architecture.X86_64,
            environment={
                "POWERTOOLS_SERVICE_NAME": "PowertoolsHelloWorld",
                "POWERTOOLS_METRICS_NAMESPACE": "PowertoolsSample",
                "LOG_LEVEL": "INFO"
            }
        )

```

```

    apigw = apigwv1.RestApi(self, "PowertoolsAPI",
    deploy_options=apigwv1.StageOptions(stage_name="dev"))

    hello_api = apigw.root.add_resource("hello")
    hello_api.add_method("GET", apigwv1.LambdaIntegration(function,
    proxy=True))

    CfnOutput(self, "apiUrl", value=f"{apigw.url}hello")

```

8. Deploy your application.

```

cd ..
cdk deploy

```

9. Get the URL of the deployed application:

```

aws cloudformation describe-stacks --stack-name HelloWorldStack --query
'Stacks[0].Outputs[?OutputKey==`apiUrl`].OutputValue' --output text

```

10. Invoke the API endpoint:

```

curl -X GET <URL_FROM_PREVIOUS_STEP>

```

If successful, you'll see this response:

```

{"message":"hello world"}

```

11. To get the traces for the function, run [sam traces](#).

```

sam traces

```

The traces output looks like this:

```

cdk destroy
```

Using ADOT to instrument your Python functions

ADOT provides fully managed Lambda [layers](#) that package everything you need to collect telemetry data using the OTel SDK. By consuming this layer, you can instrument your Lambda functions without having to modify any function code. You can also configure your layer to do custom initialization of OTel. For more information, see [Custom configuration for the ADOT Collector on Lambda](#) in the ADOT documentation.

For Python runtimes, you can add the **AWS managed Lambda layer for ADOT Python** to automatically instrument your functions. This layer works for both arm64 and x86_64 architectures. For detailed instructions on how to add this layer, see [AWS Distro for OpenTelemetry Lambda Support for Python](#) in the ADOT documentation.

Using the X-Ray SDK to instrument your Python functions

To record details about calls that your Lambda function makes to other resources in your application, you can also use the AWS X-Ray SDK for Python. To get the SDK, add the `aws-xray-sdk` package to your application's dependencies.

Example [requirements.txt](#)

```
jsonpickle==1.3
aws-xray-sdk==2.4.3
```

In your function code, you can instrument AWS SDK clients by patching the `boto3` library with the `aws_xray_sdk.core` module.

Example [function – Tracing an AWS SDK client](#)

```
import boto3
from aws_xray_sdk.core import xray_recorder
from aws_xray_sdk.core import patch_all

logger = logging.getLogger()
logger.setLevel(logging.INFO)
patch_all()

client = boto3.client('lambda')
client.get_account_settings()

def lambda_handler(event, context):
    logger.info('## ENVIRONMENT VARIABLES\r' + jsonpickle.encode(dict(**os.environ)))
    ...
```

After you add the correct dependencies and make the necessary code changes, activate tracing in your function's configuration via the Lambda console or the API.

Activating tracing with the Lambda console

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Monitoring and operations tools**.
4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.
6. Choose **Save**.

Activating tracing with the Lambda API

Configure tracing on your Lambda function with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Activating tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in a CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Lambda::Function
    Properties:
      TracingConfig:
        Mode: Active
      ...
```

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

Example [template.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      Tracing: Active
      ...
```

Interpreting an X-Ray trace

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

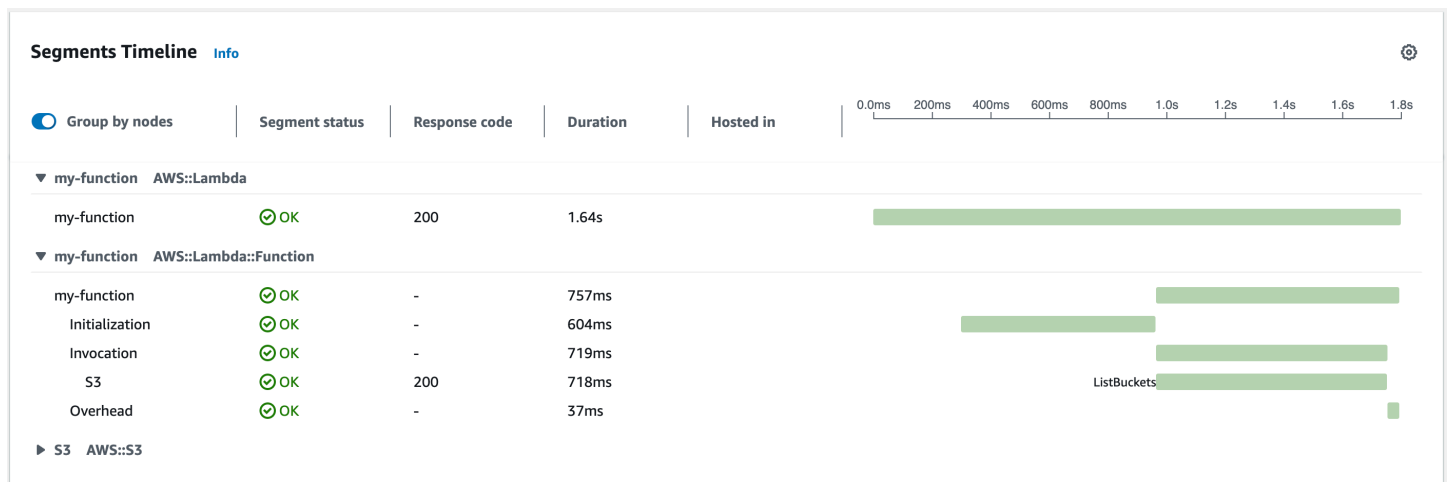

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an `Invocation` subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called "Understanding X-Ray traces"](#).

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see the [AWS X-Ray SDK for Python](#) in the *AWS X-Ray Developer Guide*.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

Storing runtime dependencies in a layer (X-Ray SDK)

If you use the X-Ray SDK to instrument AWS SDK clients your function code, your deployment package can become quite large. To avoid uploading runtime dependencies every time you update your function code, package the X-Ray SDK in a [Lambda layer](#).

The following example shows an `AWS::Serverless::LayerVersion` resource that stores the AWS X-Ray SDK for Python.

Example [template.yml](#) – Dependencies layer

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: function/.
      Tracing: Active
      Layers:
        - !Ref libs
        ...
  libs:
    Type: AWS::Serverless::LayerVersion
    Properties:
      LayerName: blank-python-lib
      Description: Dependencies for the blank-python sample app.
      ContentUri: package/.
      CompatibleRuntimes:
        - python3.11
```

With this configuration, you update the library layer only if you change your runtime dependencies. Since the function deployment package contains only your code, this can help reduce upload times.

Creating a layer for dependencies requires build changes to generate the layer archive prior to deployment. For a working example, see the [blank-python](#) sample application.

Building Lambda functions with Ruby

You can run Ruby code in AWS Lambda. Lambda provides [runtimes](#) for Ruby that run your code to process events. Your code runs in an environment that includes the AWS SDK for Ruby, with credentials from an AWS Identity and Access Management (IAM) role that you manage. To learn more about the SDK versions included with the Ruby runtimes, see [the section called “Runtime-included SDK versions”](#).

Lambda supports the following Ruby runtimes.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
Ruby 3.4	ruby3.4	Amazon Linux 2023	Mar 31, 2028	Apr 30, 2028	May 31, 2028
Ruby 3.3	ruby3.3	Amazon Linux 2023	Mar 31, 2027	Apr 30, 2027	May 31, 2027
Ruby 3.2	ruby3.2	Amazon Linux 2	Mar 31, 2026	Aug 31, 2026	Sep 30, 2026

To create a Ruby function

1. Open the [Lambda console](#).
2. Choose **Create function**.
3. Configure the following settings:
 - **Function name**: Enter a name for the function.
 - **Runtime**: Choose **Ruby 3.4**.
4. Choose **Create function**.

The console creates a Lambda function with a single source file named `lambda_function.rb`. You can edit this file and add more files in the built-in code editor. In the **DEPLOY** section, choose

Deploy to update your function's code. Then, to run your code, choose **Create test event** in the **TEST EVENTS** section.

The `lambda_function.rb` file exports a function named `lambda_handler` that takes an event object and a context object. This is the [handler function](#) that Lambda calls when the function is invoked. The Ruby function runtime gets invocation events from Lambda and passes them to the handler. In the function configuration, the handler value is `lambda_function.lambda_handler`.

When you save your function code, the Lambda console creates a .zip file archive deployment package. When you develop your function code outside of the console (using an IDE) you need to [create a deployment package](#) to upload your code to the Lambda function.

The function runtime passes a context object to the handler, in addition to the invocation event. The [context object](#) contains additional information about the invocation, the function, and the execution environment. More information is available from environment variables.

Your Lambda function comes with a CloudWatch Logs log group. The function runtime sends details about each invocation to CloudWatch Logs. It relays any [logs that your function outputs](#) during invocation. If your function returns an error, Lambda formats the error and returns it to the invoker.

Runtime-included SDK versions

The version of the AWS SDK included in the Ruby runtime depends on the runtime version and your AWS Region. The AWS SDK for Ruby is designed to be modular and is separated by AWS

service. To find the version number of a particular service gem included in the runtime you're using, create a Lambda function with code in the following format. Replace `aws-sdk-s3` and `Aws::S3` with the name of the service gems your code uses.

```
require 'aws-sdk-s3'

def lambda_handler(event:, context:)
  puts "Service gem version: #{Aws::S3::GEM_VERSION}"
  puts "Core version: #{Aws::CORE_GEM_VERSION}"
end
```

Enabling Yet Another Ruby JIT (YJIT)

The Ruby 3.2 runtime supports [YJIT](#), a lightweight, minimalistic Ruby JIT compiler. YJIT provides significantly higher performance, but also uses more memory than the Ruby interpreter. YJIT is recommended for Ruby on Rails workloads.

YJIT is not enabled by default. To enable YJIT for a Ruby 3.2 function, set the `RUBY_YJIT_ENABLE` environment variable to 1. To confirm that YJIT is enabled, print the result of the `RubyVM::YJIT.enabled?` method.

Example— Confirm that YJIT is enabled

```
puts(RubyVM::YJIT.enabled?())
# => true
```

Define Lambda function handler in Ruby

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

Topics

- [Ruby handler basics](#)
- [Code best practices for Ruby Lambda functions](#)

Ruby handler basics

In the following example, the file `function.rb` defines a handler method named `handler`. The handler function takes two objects as input and returns a JSON document.

Example `function.rb`

```
require 'json'

def handler(event:, context:)
  { event: JSON.generate(event), context: JSON.generate(context.inspect) }
end
```

In your function configuration, the `handler` setting tells Lambda where to find the handler. For the preceding example, the correct value for this setting is **`function.handler`**. It includes two names separated by a dot: the name of the file and the name of the handler method.

You can also define your handler method in a class. The following example defines a handler method named `process` on a class named `Handler` in a module named `LambdaFunctions`.

Example `source.rb`

```
module LambdaFunctions
  class Handler
    def self.process(event:, context:)
      "Hello!"
    end
  end
end
```

```
end
```

In this case, the handler setting is **`source.LambdaFunctions::Handler.process`**.

The two objects that the handler accepts are the invocation event and context. The event is a Ruby object that contains the payload that's provided by the invoker. If the payload is a JSON document, the event object is a Ruby hash. Otherwise, it's a string. The [context object](#) has methods and properties that provide information about the invocation, the function, and the execution environment.

The function handler is executed every time your Lambda function is invoked. Static code outside of the handler is executed once per instance of the function. If your handler uses resources like SDK clients and database connections, you can create them outside of the handler method to reuse them for multiple invocations.

Each instance of your function can process multiple invocation events, but it only processes one event at a time. The number of instances processing an event at any given time is your function's *concurrency*. For more information about the Lambda execution environment, see [Understanding the Lambda execution environment lifecycle](#).

Code best practices for Ruby Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function. For example, in Ruby, this may look like:

```
def lambda_handler(event:, context:)
  foo = event['foo']
  bar = event['bar']

  result = my_lambda_function(foo:, bar:)
end

def my_lambda_function(foo:, bar:)
  // MyLambdaFunction logic here
end
```

- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. For the Ruby runtime, these include the AWS SDK. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation. For functions authored in Ruby, avoid uploading the entire AWS SDK library as part of your deployment package. Instead, selectively depend on the gems which pick up components of the SDK you need (e.g. the DynamoDB or Amazon S3 SDK gems).

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Deploy Ruby Lambda functions with .zip file archives

Your AWS Lambda function's code comprises a .rb file containing your function's handler code, together with any additional dependencies (gems) your code depends on. To deploy this function code to Lambda, you use a *deployment package*. This package may either be a .zip file archive or a container image. For more information about using container images with Ruby, see [Deploy Ruby Lambda functions with container images](#).

To create your deployment package as .zip file archive, you can use your command-line tool's built-in .zip file archive utility, or any other .zip file utility such as [7zip](#). The examples shown in the following sections assume you're using a command-line zip tool in a Linux or MacOS environment. To use the same commands in Windows, you can [install the Windows Subsystem for Linux](#) to get a Windows-integrated version of Ubuntu and Bash.

Note that Lambda uses POSIX file permissions, so you may need to [set permissions for the deployment package folder](#) before you create the .zip file archive.

The example commands in the following sections use the [Bundler](#) utility to add dependencies to your deployment package. To install bundler, run the following command.

```
gem install bundler
```

Sections

- [Dependencies in Ruby](#)
- [Creating a .zip deployment package with no dependencies](#)
- [Creating a .zip deployment package with dependencies](#)
- [Creating a Ruby layer for your dependencies](#)
- [Creating .zip deployment packages with native libraries](#)
- [Creating and updating Ruby Lambda functions using .zip files](#)

Dependencies in Ruby

For Lambda functions that use the Ruby runtime, a dependency can be any Ruby gem. When you deploy your function using a .zip archive, you can either add these dependencies to your .zip file with your function code or use a Lambda layer. A layer is a separate .zip file that can contain additional code and other content. To learn more about using Lambda layers, see [Lambda layers](#).

The Ruby runtime includes the AWS SDK for Ruby. If your function uses the SDK, you don't need to bundle it with your code. However, to maintain full control of your dependencies, or to use a specific version of the SDK, you can add it to your function's deployment package. You can either include the SDK in your .zip file, or add it using a Lambda layer. Dependencies in your .zip file or in Lambda layers take precedence over versions included in the runtime. To find out which version of the SDK for Ruby is included in your runtime version, see [the section called “Runtime-included SDK versions”](#).

Under the [AWS shared responsibility model](#), you are responsible for the management of any dependencies in your functions' deployment packages. This includes applying updates and security patches. To update dependencies in your function's deployment package, first create a new .zip file and then upload it to Lambda. See [Creating a .zip deployment package with dependencies](#) and [Creating and updating Ruby Lambda functions using .zip files](#) for more information.

Creating a .zip deployment package with no dependencies

If your function code has no dependencies, your .zip file contains only the .rb file with your function's handler code. Use your preferred zip utility to create a .zip file with your .rb file at the root. If the .rb file is not at the root of your .zip file, Lambda won't be able to run your code.

To learn how to deploy your .zip file to create a new Lambda function or update an existing one, see [Creating and updating Ruby Lambda functions using .zip files](#).

Creating a .zip deployment package with dependencies

If your function code depends on additional Ruby gems, you can either add these dependencies to your .zip file with your function code or use a [Lambda layer](#). The instructions in this section show you how to include dependencies in your .zip deployment package. For instructions on how to include your dependencies in a layer, see [the section called “Creating a Ruby layer for your dependencies”](#).

Suppose your function code is saved in a file named `lambda_function.rb` in your project directory. The following example CLI commands create a .zip file named `my_deployment_package.zip` containing your function code and its dependencies.

To create the deployment package

1. In your project directory, create a `Gemfile` to specify your dependencies in.

```
bundle init
```

2. Using your preferred text editor, edit the Gemfile to specify your function's dependencies. For example, to use the TZInfo gem, edit your Gemfile to look like the following.

```
source "https://rubygems.org"  
gem "tzinfo"
```

3. Run the following command to install the gems specified in your Gemfile in your project directory. This command sets vendor/bundle as the default path for gem installations.

```
bundle config set --local path 'vendor/bundle' && bundle install
```

You should see output similar to the following.

```
Fetching gem metadata from https://rubygems.org/.....  
Resolving dependencies...  
Using bundler 2.4.13  
Fetching tzinfo 2.0.6  
Installing tzinfo 2.0.6  
...
```

Note

To install gems globally again later, run the following command.

```
bundle config set --local system 'true'
```

4. Create a .zip file archive containing the lambda_function.rb file with your function's handler code and the dependencies you installed in the previous step.

```
zip -r my_deployment_package.zip lambda_function.rb vendor
```

You should see output similar to the following.

```
adding: lambda_function.rb (deflated 37%)  
  adding: vendor/ (stored 0%)  
  adding: vendor/bundle/ (stored 0%)
```

```
adding: vendor/bundle/ruby/ (stored 0%)
adding: vendor/bundle/ruby/3.2.0/ (stored 0%)
adding: vendor/bundle/ruby/3.2.0/build_info/ (stored 0%)
adding: vendor/bundle/ruby/3.2.0/cache/ (stored 0%)
adding: vendor/bundle/ruby/3.2.0/cache/aws-eventstream-1.0.1.gem (deflated 36%)
...
```

Creating a Ruby layer for your dependencies

To learn how to package your Ruby dependencies into a Lambda layer, see [the section called “Layers”](#).

Creating .zip deployment packages with native libraries

Many common Ruby gems such as `nokogiri`, `nio4r`, and `mysql` contain native extensions written in C. When you add libraries containing C code to your deployment package, you must build your package correctly to ensure that it’s compatible with the Lambda execution environment.

For production applications, we recommend building and deploying your code using the AWS Serverless Application Model (AWS SAM). In AWS SAM use the `sam build --use-container` option to build your function inside a Lambda-like Docker container. To learn more about using AWS SAM to deploy your function code, see [Building applications](#) in the *AWS SAM Developer Guide*.

To create a .zip deployment package containing gems with native extensions without using AWS SAM, you can alternatively use a container to bundle your dependencies in an environment that is the same as the Lambda Ruby runtime environment. To complete these steps, you must have Docker installed on your build machine. To learn more about installing Docker, see [Install Docker Engine](#).

To create a .zip deployment package in a Docker container

1. Create a folder on your local build machine to save your container in. Inside that folder, create a file named `dockerfile` and paste the following code into it.

```
FROM public.ecr.aws/sam/build-ruby3.2:latest-x86_64
RUN gem update bundler
CMD "/bin/bash"
```

2. Inside the folder you created your `dockerfile` in, run the following command to create the Docker container.

```
docker build -t awsruby32 .
```

3. Navigate to the project directory containing the `.rb` file with your function's handler code and the Gemfile specifying your function's dependencies. From inside that directory, run the following command to start the Lambda Ruby container.

Linux/macOS

```
docker run --rm -it -v $PWD:/var/task -w /var/task awsruby32
```

 **Note**

In MacOS, you might see a warning informing you that the requested image's platform does not match the detected host platform. Ignore this warning.

Windows PowerShell

```
docker run --rm -it -v ${pwd}:/var/task -w /var/task awsruby32
```

When your container starts, you should see a bash prompt.

```
bash-4.2#
```

4. Configure the bundle utility to install the gems specified in your Gemfile in a local `vendor/bundle` directory and install your dependencies.

```
bash-4.2# bundle config set --local path 'vendor/bundle' && bundle install
```

5. Create the `.zip` deployment package with your function code and its dependencies. In this example, the file containing your function's handler code is named `lambda_function.rb`.

```
bash-4.2# zip -r my_deployment_package.zip lambda_function.rb vendor
```

6. Exit the container and return to your local project directory.

```
bash-4.2# exit
```

You can now use the .zip file deployment package to create or update your Lambda function. See [Creating and updating Ruby Lambda functions using .zip files](#)

Creating and updating Ruby Lambda functions using .zip files

After you have created your .zip deployment package, you can use it to create a new Lambda function or update an existing one. You can deploy your .zip package using the Lambda console, the AWS Command Line Interface, and the Lambda API. You can also create and update Lambda functions using AWS Serverless Application Model (AWS SAM) and CloudFormation.

The maximum size for a .zip deployment package for Lambda is 250 MB (unzipped). Note that this limit applies to the combined size of all the files you upload, including any Lambda layers.

The Lambda runtime needs permission to read the files in your deployment package. In Linux permissions octal notation, Lambda needs 644 permissions for non-executable files (rw-r--r--) and 755 permissions (rwxr-xr-x) for directories and executable files.

In Linux and MacOS, use the `chmod` command to change file permissions on files and directories in your deployment package. For example, to give a non-executable file the correct permissions, run the following command.

```
chmod 644 <filepath>
```

To change file permissions in Windows, see [Set, View, Change, or Remove Permissions on an Object](#) in the Microsoft Windows documentation.

Note

If you don't grant Lambda the permissions it needs to access directories in your deployment package, Lambda sets the permissions for those directories to 755 (rwxr-xr-x).

Creating and updating functions with .zip files using the console

To create a new function, you must first create the function in the console, then upload your .zip archive. To update an existing function, open the page for your function, then follow the same procedure to add your updated .zip file.

If your .zip file is less than 50MB, you can create or update a function by uploading the file directly from your local machine. For .zip files greater than 50MB, you must upload your package to an Amazon S3 bucket first. For instructions on how to upload a file to an Amazon S3 bucket using the AWS Management Console, see [Getting started with Amazon S3](#). To upload files using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

To create a new function (console)

1. Open the [Functions page](#) of the Lambda console and choose **Create Function**.
2. Choose **Author from scratch**.
3. Under **Basic information**, do the following:
 - a. For **Function name**, enter the name for your function.
 - b. For **Runtime**, select the runtime you want to use.
 - c. (Optional) For **Architecture**, choose the instruction set architecture for your function. The default architecture is x86_64. Ensure that the .zip deployment package for your function is compatible with the instruction set architecture you select.
4. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing one.
5. Choose **Create function**. Lambda creates a basic 'Hello world' function using your chosen runtime.

To upload a .zip archive from your local machine (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload the .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip file**.

5. To upload the .zip file, do the following:
 - a. Select **Upload**, then select your .zip file in the file chooser.
 - b. Choose **Open**.
 - c. Choose **Save**.

To upload a .zip archive from an Amazon S3 bucket (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload a new .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **Amazon S3 location**.
5. Paste the Amazon S3 link URL of your .zip file and choose **Save**.

Updating .zip file functions using the console code editor

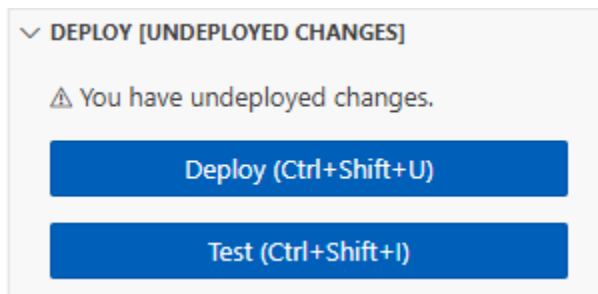

For some functions with .zip deployment packages, you can use the Lambda console's built-in code editor to update your function code directly. To use this feature, your function must meet the following criteria:

- Your function must use one of the interpreted language runtimes (Python, Node.js, or Ruby)
- Your function's deployment package must be smaller than 50 MB (unzipped).

Function code for functions with container image deployment packages cannot be edited directly in the console.

To update function code using the console code editor

1. Open the [Functions page](#) of the Lambda console and select your function.
2. Select the **Code** tab.
3. In the **Code source** pane, select your source code file and edit it in the integrated code editor.
4. In the **DEPLOY** section, choose **Deploy** to update your function's code:

Creating and updating functions with .zip files using the AWS CLI

You can use the [AWS CLI](#) to create a new function or to update an existing one using a .zip file. Use the [create-function](#) and [update-function-code](#) commands to deploy your .zip package. If your .zip file is smaller than 50MB, you can upload the .zip package from a file location on your local build machine. For larger files, you must upload your .zip package from an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

If you upload your .zip file from an Amazon S3 bucket using the AWS CLI, the bucket must be located in the same AWS Region as your function.

To create a new function using a .zip file with the AWS CLI, you must specify the following:

- The name of your function (`--function-name`)
- Your function's runtime (`--runtime`)
- The Amazon Resource Name (ARN) of your function's [execution role](#) (`--role`)
- The name of the handler method in your function code (`--handler`)

You must also specify the location of your .zip file. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda create-function --function-name myFunction \  
--runtime ruby3.2 --handler lambda_function.lambda_handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--code` option as shown in the following example command. You only need to use the `S3ObjectVersion` parameter for versioned objects.

```
aws lambda create-function --function-name myFunction \  
--runtime ruby3.2 --handler lambda_function.lambda_handler \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--code S3Bucket=amzn-s3-demo-  
bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion
```

To update an existing function using the CLI, you specify the the name of your function using the `--function-name` parameter. You must also specify the location of the .zip file you want to use to update your function code. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda update-function-code --function-name myFunction \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--s3-bucket` and `--s3-key` options as shown in the following example command. You only need to use the `--s3-object-version` parameter for versioned objects.

```
aws lambda update-function-code --function-name myFunction \  
--s3-bucket amzn-s3-demo-bucket --s3-key myFileName.zip --s3-object-version myObject  
Version
```

Creating and updating functions with .zip files using the Lambda API

To create and update functions using a .zip file archive, use the following API operations:

- [CreateFunction](#)
- [UpdateFunctionCode](#)

Creating and updating functions with .zip files using AWS SAM

The AWS Serverless Application Model (AWS SAM) is a toolkit that helps streamline the process of building and running serverless applications on AWS. You define the resources for your application in a YAML or JSON template and use the AWS SAM command line interface (AWS SAM CLI) to build,

package, and deploy your applications. When you build a Lambda function from an AWS SAM template, AWS SAM automatically creates a .zip deployment package or container image with your function code and any dependencies you specify. To learn more about using AWS SAM to build and deploy Lambda functions, see [Getting started with AWS SAM](#) in the *AWS Serverless Application Model Developer Guide*.

You can also use AWS SAM to create a Lambda function using an existing .zip file archive. To create a Lambda function using AWS SAM, you can save your .zip file in an Amazon S3 bucket or in a local folder on your build machine. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your AWS SAM template, the `AWS::Serverless::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - set to `Zip`
- `CodeUri` - set to the function code's Amazon S3 URI, path to local folder, or [FunctionCode](#) object
- `Runtime` - Set to your chosen runtime

With AWS SAM, if your .zip file is larger than 50MB, you don't need to upload it to an Amazon S3 bucket first. AWS SAM can upload .zip packages up to the maximum allowed size of 250MB (unzipped) from a location on your local build machine.

To learn more about deploying functions using .zip file in AWS SAM, see [AWS::Serverless::Function](#) in the *AWS SAM Developer Guide*.

Creating and updating functions with .zip files using CloudFormation

You can use CloudFormation to create a Lambda function using a .zip file archive. To create a Lambda function from a .zip file, you must first upload your file to an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your CloudFormation template, the `AWS::Lambda::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - Set to `Zip`
- `Code` - Enter the Amazon S3 bucket name and the .zip file name in the `S3Bucket` and `S3Key` fields
- `Runtime` - Set to your chosen runtime

The .zip file that CloudFormation generates cannot exceed 4MB. To learn more about deploying functions using .zip file in CloudFormation, see [AWS::Lambda::Function](#) in the *CloudFormation User Guide*.

Deploy Ruby Lambda functions with container images

There are three ways to build a container image for a Ruby Lambda function:

- [Using an AWS base image for Ruby](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include the [runtime interface client for Ruby](#) in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the [runtime interface client for Ruby](#) in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

Topics

- [AWS base images for Ruby](#)
- [Using an AWS base image for Ruby](#)
- [Using an alternative base image with the runtime interface client](#)

AWS base images for Ruby

AWS provides the following base images for Ruby:

Tags	Runtime	Operating system	Dockerfile	Deprecation
3.4	Ruby 3.4	Amazon Linux 2023	Dockerfile for Ruby 3.4 on GitHub	Mar 31, 2028
3.3	Ruby 3.3	Amazon Linux 2023	Dockerfile for Ruby 3.3 on GitHub	Mar 31, 2027
3.2	Ruby 3.2	Amazon Linux 2	Dockerfile for Ruby 3.2 on GitHub	Mar 31, 2026

Amazon ECR repository: gallery.ecr.aws/lambda/ruby

Using an AWS base image for Ruby

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Ruby

Creating an image from a base image

To create a container image for Ruby

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new file called `Gemfile`. This is where you list your application's required RubyGems packages. The AWS SDK for Ruby is available from RubyGems. You should choose specific AWS service gems to install. For example, to use the [Ruby gem for Lambda](#), your Gemfile should look like this:

```
source 'https://rubygems.org'

gem 'aws-sdk-lambda'
```

Alternatively, the [aws-sdk](#) gem contains every available AWS service gem. This gem is very large. We recommend that you use it only if you depend on many AWS services.

3. Install the dependencies specified in the Gemfile using [bundle install](#).

```
bundle install
```

4. Create a new file called `lambda_function.rb`. You can add the following sample function code to the file for testing, or use your own.

Example Ruby function

```
module LambdaFunction
  class Handler
    def self.process(event:, context:)
      "Hello from Lambda!"
    end
  end
end
```

5. Create a new Dockerfile. The following is an example Dockerfile that uses an [AWS base image](#). This Dockerfile uses the following configuration:
 - Set the FROM property to the URI of the base image.
 - Use the COPY command to copy the function code and runtime dependencies to `{LAMBDA_TASK_ROOT}`, a [Lambda-defined environment variable](#).
 - Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-

privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/ruby:3.4

# Copy Gemfile and Gemfile.lock
COPY Gemfile Gemfile.lock ${LAMBDA_TASK_ROOT}/

# Install Bundler and the specified gems
RUN gem install bundler:2.4.20 && \
    bundle config set --local path 'vendor/bundle' && \
    bundle install

# Copy function code
COPY lambda_function.rb ${LAMBDA_TASK_ROOT}/

# Set the CMD to your handler (could also be done as a parameter override outside
# of the Dockerfile)
CMD [ "lambda_function.LambdaFunction::Handler.process" ]
```

6. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

1. Start the Docker image with the **docker run** command. In this example, `docker-image` is the image name and `test` is the tag.

```
docker run --platform linux/amd64 -p 9000:8080 docker-image:test
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

2. From a new terminal window, post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType "application/json"
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Using an alternative base image with the runtime interface client

If you use an [OS-only base image](#) or an alternative base image, you must include the runtime interface client in your image. The runtime interface client extends the [Runtime API](#), which manages the interaction between Lambda and your function code.

Install the [Lambda runtime interface client for Ruby](#) using the RubyGems.org package manager:

```
gem install aws_lambda_ri
```

You can also download the [Ruby runtime interface client](#) from GitHub.

The following example demonstrates how to build a container image for Ruby using a non-AWS base image. The example Dockerfile uses an official Ruby base image. The Dockerfile includes the runtime interface client.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)

- The Docker [buildx plugin](#).
- Ruby

Creating an image from an alternative base image

To create a container image for Ruby using an alternative base image

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Create a new file called `Gemfile`. This is where you list your application's required RubyGems packages. The AWS SDK for Ruby is available from RubyGems. You should choose specific AWS service gems to install. For example, to use the [Ruby gem for Lambda](#), your `Gemfile` should look like this:

```
source 'https://rubygems.org'

gem 'aws-sdk-lambda'
```

Alternatively, the [aws-sdk](#) gem contains every available AWS service gem. This gem is very large. We recommend that you use it only if you depend on many AWS services.

3. Install the dependencies specified in the `Gemfile` using [bundle install](#).

```
bundle install
```

4. Create a new file called `lambda_function.rb`. You can add the following sample function code to the file for testing, or use your own.

Example Ruby function

```
module LambdaFunction
  class Handler
    def self.process(event:, context:)
      "Hello from Lambda!"
    end
  end
end
```

5. Create a new Dockerfile. The following Dockerfile uses a Ruby base image instead of an [AWS base image](#). The Dockerfile includes the [runtime interface client for Ruby](#), which makes the image compatible with Lambda. Alternatively, you can add the runtime interface client to your application's Gemfile.
 - Set the FROM property to the Ruby base image.
 - Create a directory for the function code and an environment variable that points to that directory. In this example, the directory is /var/task, which mirrors the Lambda execution environment. However, you can choose any directory for the function code because the Dockerfile doesn't use an AWS base image.
 - Set the ENTRYPOINT to the module that you want the Docker container to run when it starts. In this case, the module is the runtime interface client.
 - Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM ruby:2.7

# Install the runtime interface client for Ruby
RUN gem install aws_lambda_ric

# Add the runtime interface client to the PATH
ENV PATH="/usr/local/bundle/bin:${PATH}"

# Create a directory for the Lambda function
ENV LAMBDA_TASK_ROOT=/var/task
RUN mkdir -p ${LAMBDA_TASK_ROOT}
WORKDIR ${LAMBDA_TASK_ROOT}

# Copy Gemfile and Gemfile.lock
COPY Gemfile Gemfile.lock ${LAMBDA_TASK_ROOT}/

# Install Bundler and the specified gems
RUN gem install bundler:2.4.20 && \
```

```
bundle config set --local path 'vendor/bundle' && \
bundle install

# Copy function code
COPY lambda_function.rb ${LAMBDA_TASK_ROOT}/

# Set runtime interface client as default command for the container runtime
ENTRYPOINT [ "aws_lambda_ric" ]

# Set the CMD to your handler (could also be done as a parameter override outside
of the Dockerfile)
CMD [ "lambda_function.LambdaFunction::Handler.process" ]
```

6. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test
.
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test the image. You can [build the emulator into your image](#) or use the following procedure to install it on your local machine.

To install and run the runtime interface emulator on your local machine

1. From your project directory, run the following command to download the runtime interface emulator (x86-64 architecture) from GitHub and install it on your local machine.

Linux/macOS

```
mkdir -p ~/.aws-lambda-rie && \  
  curl -Lo ~/.aws-lambda-rie/aws-lambda-rie https://github.com/aws/aws-lambda-  
runtime-interface-emulator/releases/latest/download/aws-lambda-rie && \  
  chmod +x ~/.aws-lambda-rie/aws-lambda-rie
```

To install the arm64 emulator, replace the GitHub repository URL in the previous command with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/  
download/aws-lambda-rie-arm64
```

PowerShell

```
$dirPath = "$HOME\.aws-lambda-rie"  
if (-not (Test-Path $dirPath)) {  
    New-Item -Path $dirPath -ItemType Directory  
}  
  
$downloadLink = "https://github.com/aws/aws-lambda-runtime-interface-emulator/  
releases/latest/download/aws-lambda-rie"  
$destinationPath = "$HOME\.aws-lambda-rie\aws-lambda-rie"  
Invoke-WebRequest -Uri $downloadLink -OutFile $destinationPath
```

To install the arm64 emulator, replace the `$downloadLink` with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/  
download/aws-lambda-rie-arm64
```

2. Start the Docker image with the **docker run** command. Note the following:

- `docker-image` is the image name and `test` is the tag.
- `aws_lambda_rie lambda_function.LambdaFunction::Handler.process` is the ENTRYPOINT followed by the CMD from your Dockerfile.

Linux/macOS

```
docker run --platform linux/amd64 -d -v ~/.aws-lambda-rie:/aws-lambda -p
9000:8080 \
  --entrypoint /aws-lambda/aws-lambda-rie \
  docker-image:test \
  aws_lambda_rie lambda_function.LambdaFunction::Handler.process
```

PowerShell

```
docker run --platform linux/amd64 -d -v "$HOME\.aws-lambda-rie:/aws-lambda" -p
9000:8080 `
--entrypoint /aws-lambda/aws-lambda-rie `
docker-image:test `
aws_lambda_rie lambda_function.LambdaFunction::Handler.process
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

3. Post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following Invoke-WebRequest command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{} ' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType  
"application/json"
```

4. Get the container ID.

```
docker ps
```

5. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

 **Note**

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:

- `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
- Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \
  --function-name hello-world \
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --publish
```

Working with layers for Ruby Lambda functions

Use [Lambda layers](#) to package code and dependencies that you want to reuse across multiple functions. Layers usually contain library dependencies, a [custom runtime](#), or configuration files. Creating a layer involves three general steps:

1. Package your layer content. This means creating a .zip file archive that contains the dependencies you want to use in your functions.
2. Create the layer in Lambda.
3. Add the layer to your functions.

Topics

- [Package your layer content](#)
- [Create the layer in Lambda](#)
- [Using gems from layers in a function](#)
- [Add the layer to your function](#)
- [Sample app](#)

Package your layer content

To create a layer, bundle your packages into a .zip file archive that meets the following requirements:

- Create the layer using the same Ruby version that you plan to use for the Lambda function. For example, if you create your layer for Ruby 3.4, use the Ruby 3.4 runtime for your function.
- Your layer's .zip file must use one of these directory structures:
 - `ruby/gems/x.x.x` (where `x.x.x` is your Ruby version, for example `3.4.0`)
 - `ruby/lib`

For more information, see [Layer paths for each Lambda runtime](#).

- The packages in your layer must be compatible with Linux. Lambda functions run on Amazon Linux.

You can create layers that contain either third-party Ruby gems or your own Ruby modules and classes. Many popular Ruby gems contain native extensions (C code) that must be compiled for the Lambda Linux environment.

Pure Ruby gems

Pure Ruby gems contain only Ruby code and don't require compilation. These gems are simpler to package and work across different platforms.

To create a layer using pure Ruby gems

1. Create a Gemfile to specify the pure Ruby gems you want to include in your layer:

Example Gemfile

```
source 'https://rubygems.org'

gem 'tzinfo'
```

2. Install the gems to vendor/bundle directory using Bundler:

```
bundle config set --local path vendor/bundle
bundle install
```

3. Copy the installed gems to the directory structure that Lambda requires (ruby/gems/3.4.0):

```
mkdir -p ruby/gems/3.4.0
cp -r vendor/bundle/ruby/3.4.0*/** ruby/gems/3.4.0/
```

4. Zip the layer content:

Linux/macOS

```
zip -r layer.zip ruby/
```

PowerShell

```
Compress-Archive -Path .\ruby -DestinationPath .\layer.zip
```

The directory structure of your .zip file should look like this:

```
ruby/  
### gems/  
  ### 3.4.0/  
    ### gems/  
    #   ### concurrent-ruby-1.3.5/  
    #   ### tzinfo-2.0.6/  
  ### specifications/  
  ### cache/  
  ### build_info/  
  ### (other bundler directories)
```

Note

You must require each gem individually in your function code. You can't use `bundler/setup` or `Bundler.require`. For more information, see [Using gems from layers in a function](#).

Gems with native extensions

Many popular Ruby gems contain native extensions (C code) that must be compiled for the target platform. Popular gems with native extensions include [nokogiri](#), [pg](#), [mysql2](#), [sqlite3](#), and [ffi](#). These gems must be built in a Linux environment that is compatible with the Lambda runtime.

To create a layer using gems with native extensions

1. Create a Gemfile.

Example Gemfile

```
source 'https://rubygems.org'  
  
gem 'nokogiri'  
gem 'httparty'
```

2. Use Docker to build the gems in a Linux environment that is compatible with Lambda. Specify an [AWS base image](#) in your Dockerfile:

Example Dockerfile for Ruby 3.4

```
FROM public.ecr.aws/lambda/ruby:3.4

# Copy Gemfile
COPY Gemfile ./

# Install system dependencies for native extensions
RUN dnf update -y && \
    dnf install -y gcc gcc-c++ make

# Configure bundler and install gems
RUN bundle config set --local path vendor/bundle && \
    bundle install

# Create the layer structure
RUN mkdir -p ruby/gems/3.4.0 && \
    cp -r vendor/bundle/ruby/3.4.0*/ ruby/gems/3.4.0/

# Create the layer zip file
RUN zip -r layer.zip ruby/
```

3. Build the image and extract the layer:

```
docker build -t ruby-layer-builder .
docker run --rm -v $(pwd):/output --entrypoint cp ruby-layer-builder layer.zip /
output/
```

This builds the gems in the correct Linux environment and copies the `layer.zip` file to your local directory. The directory structure of your `.zip` file should look like this:

```
ruby/
### gems/
  ### 3.4.0/
    ### gems/
      # ### bigdecimal-3.2.2/
      # ### csv-3.3.5/
      # ### httparty-0.23.1/
      # ### mini_mime-1.1.5/
      # ### multi_xml-0.7.2/
      # ### nokogiri-1.18.8-x86_64-linux-gnu/
```

```
#   ### racc-1.8.1/  
### build_info/  
### cache/  
### specifications/  
### (other bundler directories)
```

Note

You must require each gem individually in your function code. You can't use `bundler/setup` or `Bundler.require`. For more information, see [Using gems from layers in a function](#).

Custom Ruby modules

To create a layer using your own code

1. Create the required directory structure for your layer:

```
mkdir -p ruby/lib
```

2. Create your Ruby modules in the `ruby/lib` directory. The following example module validates orders by confirming that they contain the required information.

Example `ruby/lib/order_validator.rb`

```
require 'json'  
  
module OrderValidator  
  class ValidationError < StandardError; end  
  
  def self.validate_order(order_data)  
    # Validates an order and returns formatted data  
    required_fields = %w[product_id quantity]  
  
    # Check required fields  
    missing_fields = required_fields.reject { |field| order_data.key?(field) }  
    unless missing_fields.empty?  
      raise ValidationError, "Missing required fields: #{missing_fields.join(', ')}"  
    end  
  end  
end
```

```
# Validate quantity
quantity = order_data['quantity']
unless quantity.is_a?(Integer) && quantity > 0
  raise ValidationError, 'Quantity must be a positive integer'
end

# Format and return the validated data
{
  'product_id' => order_data['product_id'].to_s,
  'quantity' => quantity,
  'shipping_priority' => order_data.fetch('priority', 'standard')
}
end

def self.format_response(status_code, body)
  # Formats the API response
  {
    statusCode: status_code,
    body: JSON.generate(body)
  }
end
end
```

3. Zip the layer content:

Linux/macOS

```
zip -r layer.zip ruby/
```

PowerShell

```
Compress-Archive -Path .\ruby -DestinationPath .\layer.zip
```

The directory structure of your .zip file should look like this:

```
ruby/
### lib/
### order_validator.rb
```

4. In your function, require and use the modules. You must require each gem individually in your function code. You can't use `bundler/setup` or `Bundler.require`. For more information, see [Using gems from layers in a function](#). Example:

```
require 'json'
require 'order_validator'

def lambda_handler(event:, context:)
  begin
    # Parse the order data from the event body
    order_data = JSON.parse(event['body'] || '{}')

    # Validate and format the order
    validated_order = OrderValidator.validate_order(order_data)

    OrderValidator.format_response(200, {
      message: 'Order validated successfully',
      order: validated_order
    })
  rescue OrderValidator::ValidationError => e
    OrderValidator.format_response(400, {
      error: e.message
    })
  rescue => e
    OrderValidator.format_response(500, {
      error: 'Internal server error'
    })
  end
end
```

You can use the following [test event](#) to invoke the function:

```
{
  "body": "{\"product_id\": \"ABC123\", \"quantity\": 2, \"priority\": \"express\"}"
}
```

Expected response:

```
{
  "statusCode": 200,
```

```
"body": "{\"message\":\"Order validated successfully\\\", \"order\":{\"product_id\": \"ABC123\\\", \"quantity\":2, \"shipping_priority\":\"express\"}}\"
}
```

Create the layer in Lambda

You can publish your layer using either the AWS CLI or the Lambda console.

AWS CLI

Run the [publish-layer-version](#) AWS CLI command to create the Lambda layer:

```
aws lambda publish-layer-version --layer-name my-layer --zip-file fileb://layer.zip
--compatible-runtimes ruby3.4
```

The [compatible runtimes](#) parameter is optional. When specified, Lambda uses this parameter to filter layers in the Lambda console.

Console

To create a layer (console)

1. Open the [Layers page](#) of the Lambda console.
2. Choose **Create layer**.
3. Choose **Upload a .zip file**, and then upload the .zip archive that you created earlier.
4. (Optional) For **Compatible runtimes**, choose the Ruby runtime that corresponds to the Ruby version you used to build your layer.
5. Choose **Create**.

Using gems from layers in a function

In your function code, you must explicitly require each gem that you want to use. Bundler commands such as `bundler/setup` and `Bundler.require` are not supported. Here's how to properly use gems from a layer in a Lambda function:

```
# Correct: Use explicit requires for each gem
```

```
require 'nokogiri'
require 'httparty'

def lambda_handler(event:, context:)
  # Use the gems directly
  doc = Nokogiri::HTML(event['html'])
  response = HTTParty.get(event['url'])
  # ... rest of your function
end

# Incorrect: These Bundler commands will not work
# require 'bundler/setup'
# Bundler.require
```

Add the layer to your function

AWS CLI

To attach the layer to your function, run the [update-function-configuration](#) AWS CLI command. For the `--layers` parameter, use the layer ARN. The ARN must specify the version (for example, `arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1`). For more information, see [Layers and layer versions](#).

```
aws lambda update-function-configuration --function-name my-function --cli-binary-format raw-in-base64-out --layers "arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1"
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

Console

To add a layer to a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function.
3. Scroll down to the **Layers** section, and then choose **Add a layer**.
4. Under **Choose a layer**, select **Custom layers**, and then choose your layer.

 **Note**

If you didn't add a [compatible runtime](#) when you created the layer, your layer won't be listed here. You can specify the layer ARN instead.

5. Choose **Add**.

Sample app

For more examples of how to use Lambda layers, see the [layer-ruby](#) sample application in the AWS Lambda Developer Guide GitHub repository. This application includes a layer that contains the [tzinfo](#) library. After creating the layer, you can deploy and invoke the corresponding function to confirm that the layer works as expected.

Using the Lambda context object to retrieve Ruby function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides methods and properties that provide information about the invocation, function, and execution environment.

Context methods

- `get_remaining_time_in_millis` – Returns the number of milliseconds left before the execution times out.

Context properties

- `function_name` – The name of the Lambda function.
- `function_version` – The [version](#) of the function.
- `invoked_function_arn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `memory_limit_in_mb` – The amount of memory that's allocated for the function.
- `aws_request_id` – The identifier of the invocation request.
- `log_group_name` – The log group for the function.
- `log_stream_name` – The log stream for the function instance.
- `deadline_ms` – The date that the execution times out, in Unix time milliseconds.
- `identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
- `client_context` – (mobile apps) Client context that's provided to Lambda by the client application.

Log and monitor Ruby Lambda functions

AWS Lambda automatically monitors Lambda functions on your behalf and sends logs to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation to the log stream, and relays logs and other output from your function's code. For more information, see [Sending Lambda function logs to CloudWatch Logs](#).

This page describes how to produce log output from your Lambda function's code, and access logs using the AWS Command Line Interface, the Lambda console, or the CloudWatch console.

Sections

- [Creating a function that returns logs](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)
- [Viewing logs using the AWS Command Line Interface \(AWS CLI\)](#)
- [Deleting logs](#)
- [Working with the Ruby logger library](#)

Creating a function that returns logs

To output logs from your function code, you can use `puts` statements, or any logging library that writes to `stdout` or `stderr`. The following example logs the values of environment variables and the event object.

Example `lambda_function.rb`

```
# lambda_function.rb

def handler(event:, context:)
  puts "## ENVIRONMENT VARIABLES"
  puts ENV.to_a
  puts "## EVENT"
  puts event.to_a
end
```

Example log format

```
START RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95 Version: $LATEST
## ENVIRONMENT VARIABLES
environ({'AWS_LAMBDA_LOG_GROUP_NAME': '/aws/lambda/my-function',
  'AWS_LAMBDA_LOG_STREAM_NAME': '2020/01/31/[$LATEST]3893xmpl7fac4485b47bb75b671a283c',
  'AWS_LAMBDA_FUNCTION_NAME': 'my-function', ...})
## EVENT
{'key': 'value'}
END RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95
REPORT RequestId: 8f507cfc-xmpl-4697-b07a-ac58fc914c95  Duration: 15.74 ms  Billed
  Duration: 147 ms Memory Size: 128 MB Max Memory Used: 56 MB  Init Duration: 130.49 ms
XRAY TraceId: 1-5e34a614-10bdxmpl1f1fb44f07bc535a1  SegmentId: 07f5xmpl2d1f6f85
  Sampled: true
```

The Ruby runtime logs the START, END, and REPORT lines for each invocation. The report line provides the following details.

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

For more detailed logs, use the [the section called “Working with the Ruby logger library”](#).

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
```

```

    "StatusCode": 200,
    "LogResult":
      "U1RBULQgUmVxdWVzdElkOiA4N2QwNDRIOC1mMTU0LTExZTgtOGNkYS0yOTc0YzVlNGZiMjEgVmVyc2lva... ",
    "ExecutedVersion": "$LATEST"
  }

```

Example decode the logs

In the same command prompt, use the base64 utility to decode the logs. The following example shows how to retrieve base64-encoded logs for my-function.

```

aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode

```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```

START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0""",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB

```

The base64 utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"//g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
{
  "events": [
    {
      "timestamp": 1559763003171,
      "message": "START RequestId: 4ce9340a-b765-490f-ad8a-02ab3415e2bf Version:
$LATEST\n",
      "ingestionTime": 1559763003309
    },
    {
```

```

        "timestamp": 1559763003173,
        "message": "2019-06-05T19:30:03.173Z\t4ce9340a-b765-490f-ad8a-02ab3415e2bf

}

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Working with the Ruby logger library

The Ruby [logger library](#) returns streamlined logs that are easily read. Use the logger utility to output detailed information, messages, and errors codes related to your function.

```
# lambda_function.rb
```

```
require 'logger'

def handler(event:, context:)
  logger = Logger.new($stdout)
  logger.info('## ENVIRONMENT VARIABLES')
  logger.info(ENV.to_a)
  logger.info('## EVENT')
  logger.info(event)
  event.to_a
end
```

The output from `logger` includes the log level, timestamp, and request ID.

Instrumenting Ruby code in AWS Lambda

Lambda integrates with AWS X-Ray to enable you to trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, from the frontend API to storage and database on the backend. By simply adding the X-Ray SDK library to your build configuration, you can record errors and latency for any call that your function makes to an AWS service.

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Monitoring and operations tools**.
4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.

6. Choose **Save**.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

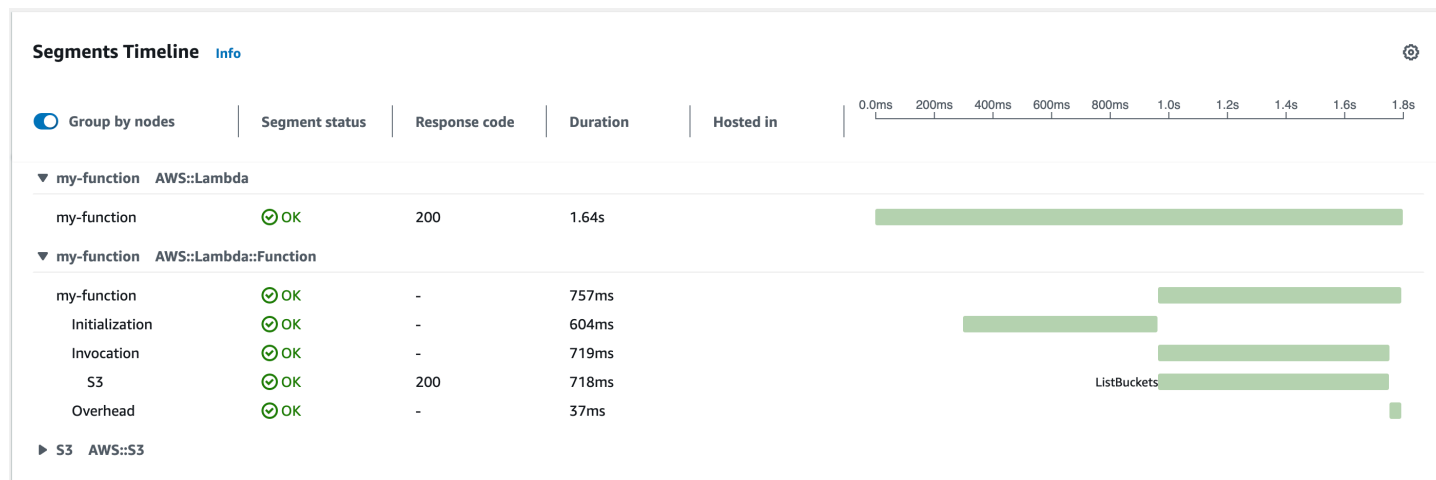

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an `Invocation` subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called "Understanding X-Ray traces"](#).

You can instrument your handler code to record metadata and trace downstream calls. To record detail about calls that your handler makes to other resources and services, use the X-Ray SDK for Ruby. To get the SDK, add the `aws-xray-sdk` package to your application's dependencies.

Example [blank-ruby/function/Gemfile](#)

```
# Gemfile
source 'https://rubygems.org'

gem 'aws-xray-sdk', '0.11.4'
gem 'aws-sdk-lambda', '1.39.0'
gem 'test-unit', '3.3.5'
```

To instrument AWS SDK clients, require the `aws-xray-sdk/lambda` module after creating a client in initialization code.

Example [blank-ruby/function/lambda_function.rb](#) – Tracing an AWS SDK client

```
# lambda_function.rb
require 'logger'
require 'json'
require 'aws-sdk-lambda'
$client = Aws::Lambda::Client.new()
$client.get_account_settings()

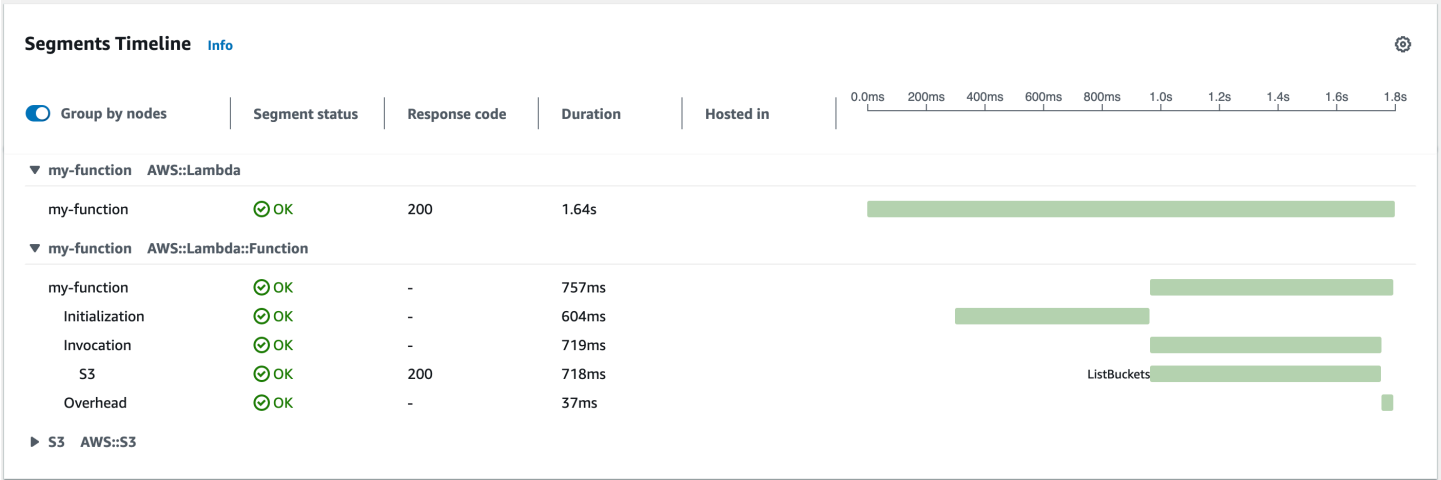

require 'aws-xray-sdk/lambda'

def lambda_handler(event:, context:)
  logger = Logger.new($stdout)
  ...
```

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

 **Note**

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an Invocation subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called “Understanding X-Ray traces”](#).

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see [The X-Ray SDK for Ruby](#) in the AWS X-Ray Developer Guide.

Sections

- [Enabling active tracing with the Lambda API](#)
- [Enabling active tracing with CloudFormation](#)
- [Storing runtime dependencies in a layer](#)

Enabling active tracing with the Lambda API

To manage tracing configuration with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \  
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Enabling active tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in an CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:  
  function:  
    Type: AWS::Lambda::Function  
    Properties:  
      TracingConfig:  
        Mode: Active  
      ...
```

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

Example [template.yml](#) – Tracing configuration

```
Resources:  
  function:  
    Type: AWS::Serverless::Function  
    Properties:  
      Tracing: Active  
      ...
```

Storing runtime dependencies in a layer

If you use the X-Ray SDK to instrument AWS SDK clients your function code, your deployment package can become quite large. To avoid uploading runtime dependencies every time you update your function code, package the X-Ray SDK in a [Lambda layer](#).

The following example shows an `AWS::Serverless::LayerVersion` resource that stores X-Ray SDK for Ruby.

Example [template.yml](#) – Dependencies layer

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: function/.
      Tracing: Active
      Layers:
        - !Ref libs
        ...
  libs:
    Type: AWS::Serverless::LayerVersion
    Properties:
      LayerName: blank-ruby-lib
      Description: Dependencies for the blank-ruby sample app.
      ContentUri: lib/.
      CompatibleRuntimes:
        - ruby2.5
```

With this configuration, you update the library layer only if you change your runtime dependencies. Since the function deployment package contains only your code, this can help reduce upload times.

Creating a layer for dependencies requires build changes to generate the layer archive prior to deployment. For a working example, see the [blank-ruby](#) sample application.

Building Lambda functions with Java

You can run Java code in AWS Lambda. Lambda provides [runtimes](#) for Java that run your code to process events. Your code runs in an Amazon Linux environment that includes AWS credentials from an AWS Identity and Access Management (IAM) role that you manage.

Lambda supports the following Java runtimes.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
Java 25	java25	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
Java 21	java21	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
Java 17	java17	Amazon Linux 2	Jun 30, 2027	Jul 31, 2027	Aug 31, 2027
Java 11	java11	Amazon Linux 2	Jun 30, 2027	Jul 31, 2027	Aug 31, 2027
Java 8	java8.a12	Amazon Linux 2	Jun 30, 2027	Jul 31, 2027	Aug 31, 2027

AWS provides the following libraries for Java functions. These libraries are available through [Maven Central Repository](#).

- [com.amazonaws:aws-lambda-java-core](#) (required) – Defines handler method interfaces and the context object that the runtime passes to the handler. If you define your own input types, this is the only library that you need.
- [com.amazonaws:aws-lambda-java-events](#) – Input types for events from services that invoke Lambda functions.
- [com.amazonaws:aws-lambda-java-log4j2](#) – An appender library for Apache Log4j 2 that you can use to add the request ID for the current invocation to your [function logs](#).

- [AWS SDK for Java 2.0](#) – The official AWS SDK for the Java programming language.

Add these libraries to your build definition as follows:

Gradle

```
dependencies {  
    implementation 'com.amazonaws:aws-lambda-java-core:1.2.2'  
    implementation 'com.amazonaws:aws-lambda-java-events:3.11.1'  
    runtimeOnly 'com.amazonaws:aws-lambda-java-log4j2:1.5.1'  
}
```

Maven

```
<dependencies>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-core</artifactId>  
    <version>1.2.2</version>  
  </dependency>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-events</artifactId>  
    <version>3.11.1</version>  
  </dependency>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-log4j2</artifactId>  
    <version>1.5.1</version>  
  </dependency>  
</dependencies>
```

Important

Don't use private components of the JDK API, such as private fields, methods, or classes. Non-public API components can change or be removed in any update, causing your application to break.

To create a Java function

1. Open the [Lambda console](#).
2. Choose **Create function**.
3. Configure the following settings:
 - **Function name:** Enter a name for the function.
 - **Runtime:** Choose **Java 25**.
4. Choose **Create function**.

The console creates a Lambda function with a handler class named `Hello`. Since Java is a compiled language, you can't view or edit the source code in the Lambda console, but you can modify its configuration, invoke it, and configure triggers.

Note

To get started with application development in your local environment, deploy one of the [sample applications](#) available in this guide's GitHub repository.

The `Hello` class has a function named `handleRequest` that takes an event object and a context object. This is the [handler function](#) that Lambda calls when the function is invoked. The Java function runtime gets invocation events from Lambda and passes them to the handler. In the function configuration, the handler value is `example.Hello::handleRequest`.

To update the function's code, you create a deployment package, which is a .zip file archive that contains your function code. As your function development progresses, you will want to store your function code in source control, add libraries, and automate deployments. Start by [creating a deployment package](#) and updating your code at the command line.

The function runtime passes a context object to the handler, in addition to the invocation event. The [context object](#) contains additional information about the invocation, the function, and the execution environment. More information is available from environment variables.

Your Lambda function comes with a CloudWatch Logs log group. The function runtime sends details about each invocation to CloudWatch Logs. It relays any [logs that your function outputs](#) during invocation. If your function returns an error, Lambda formats the error and returns it to the invoker.

Define Lambda function handler in Java

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in Java, including options for project setup, naming conventions, and best practices. This page also includes an example of a Java Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (Amazon S3) bucket. For information about how to deploy your function after writing it, see [the section called “Deploy .zip file archives”](#) or [the section called “Deploy container images”](#).

Setting up your Java handler project

When working with Lambda functions in Java, the process involves writing your code, compiling it, and deploying the compiled artifacts to Lambda. You can initialize a Java Lambda project in various ways. For instance, you can use tools like the [Maven Archetype for Lambda functions](#), the AWS SAM CLI [sam init command](#), or even a standard Java project setup in your preferred IDE, such as IntelliJ IDEA or Visual Studio Code. Alternatively, you can create the required file structure manually.

A typical Java Lambda function project follows this general structure:

```
/project-root
```

```
# src
# main
# java
# example
#   OrderHandler.java (contains main handler)
#   <other_supporting_classes>
# build.gradle OR pom.xml
```

You can use either Maven or Gradle to build your project and manage dependencies.

The main handler logic for your function resides in a Java file under the `src/main/java/example` directory. In the example on this page, we name this file `OrderHandler.java`. Apart from this file, you can include additional Java classes as needed. When deploying your function to Lambda, make sure you specify the Java class that contains the main handler method that Lambda should invoke during an invocation.

Example Java Lambda function code

The following example Java 21 Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket.

Example `OrderHandler.java` Lambda function

```
package example;

import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.RequestHandler;
import software.amazon.awssdk.core.sync.RequestBody;
import software.amazon.awssdk.services.s3.S3Client;
import software.amazon.awssdk.services.s3.model.PutObjectRequest;
import software.amazon.awssdk.services.s3.model.S3Exception;

import java.nio.charset.StandardCharsets;

/**
 * Lambda handler for processing orders and storing receipts in S3.
 */
public class OrderHandler implements RequestHandler<OrderHandler.Order, String> {

    private static final S3Client S3_CLIENT = S3Client.builder().build();

    /**
     * Record to model the input event.
```

```

    */
    public record Order(String orderId, double amount, String item) {}

    @Override
    public String handleRequest(Order event, Context context) {
        try {
            // Access environment variables
            String bucketName = System.getenv("RECEIPT_BUCKET");
            if (bucketName == null || bucketName.isEmpty()) {
                throw new IllegalArgumentException("RECEIPT_BUCKET environment variable
is not set");
            }

            // Create the receipt content and key destination
            String receiptContent = String.format("OrderID: %s\nAmount: $%.2f\nItem:
%s",
                event.orderId(), event.amount(), event.item());
            String key = "receipts/" + event.orderId() + ".txt";

            // Upload the receipt to S3
            uploadReceiptToS3(bucketName, key, receiptContent);

            context.getLogger().log("Successfully processed order " + event.orderId() +
                " and stored receipt in S3 bucket " + bucketName);
            return "Success";

        } catch (Exception e) {
            context.getLogger().log("Failed to process order: " + e.getMessage());
            throw new RuntimeException(e);
        }
    }

    private void uploadReceiptToS3(String bucketName, String key, String
receiptContent) {
        try {
            PutObjectRequest putObjectRequest = PutObjectRequest.builder()
                .bucket(bucketName)
                .key(key)
                .build();

            // Convert the receipt content to bytes and upload to S3
            S3_CLIENT.putObject(putObjectRequest,
RequestBody.fromBytes(receiptContent.getBytes(StandardCharsets.UTF_8)));
        } catch (S3Exception e) {

```

```
        throw new RuntimeException("Failed to upload receipt to S3: " +
            e.awsErrorDetails().errorMessage(), e);
    }
}
```

This `OrderHandler.java` file contains the following sections of code:

- `package example`: In Java, this can be anything, but it must match the directory structure of your project. Here, we use `package example` because the directory structure is `src/main/java/example`.
- `import` statements: Use these to import Java classes that your Lambda function requires.
- `public class OrderHandler ...`: This defines your Java class, and must be a [valid class definition](#).
- `private static final S3Client S3_CLIENT ...`: This initializes an S3 client outside of any of the class's methods. This causes Lambda to run this code during the [initialization phase](#).
- `public record Order ...`: Define the shape of the expected input event in this custom Java [record](#).
- `public String handleRequest(Order event, Context context)`: This is the **main handler method**, which contains your main application logic.
- `private void uploadReceiptToS3(...)` {}: This is a helper method that's referenced by the main `handleRequest` handler method.

Sample `build.gradle` and `pom.xml` file

The following `build.gradle` or `pom.xml` file accompanies this function.

`build.gradle`

```
plugins {
    id 'java'
}

repositories {
    mavenCentral()
}

dependencies {
```

```

        implementation 'com.amazonaws:aws-lambda-java-core:1.2.3'
        implementation 'software.amazon.awssdk:s3:2.28.29'
        implementation 'org.slf4j:slf4j-nop:2.0.16'
    }

    task buildZip(type: Zip) {
        from compileJava
        from processResources
        into('lib') {
            from configurations.runtimeClasspath
        }
    }

    java {
        sourceCompatibility = JavaVersion.VERSION_21
        targetCompatibility = JavaVersion.VERSION_21
    }

    build.dependsOn buildZip

```

pom.xml

```

<project xmlns="http://maven.apache.org/POM/4.0.0" xmlns:xsi="http://

</project>
```

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

Note

This function may require additional configuration settings to run successfully without timing out. We recommend configuring 256 MB of memory, and a 10 second timeout. The first invocation may take extra time due to a [cold start](#). Subsequent invocations should run much faster due to reuse of the execution environment.

Valid class definitions for Java handlers

To define your class, the [aws-lambda-java-core](#) library defines two interfaces for handler methods. Use the provided interfaces to simplify handler configuration and validate the method signature at compile time.

- [com.amazonaws.services.lambda.runtime.RequestHandler](#)
- [com.amazonaws.services.lambda.runtime.RequestStreamHandler](#)

The `RequestHandler` interface is a generic type that takes two parameters: the input type and the output type. Both types must be objects. In this example, our `OrderHandler` class implements `RequestHandler<OrderHandler.Order, String>`. The input type is the `Order` record we define within the class, and the output type is `String`.

```
public class OrderHandler implements RequestHandler<OrderHandler.Order, String> {
```

```
    ...  
}
```

When you use this interface, the Java runtime deserializes the event into the object with the input type, and serializes the output into text. Use this interface when the built-in serialization works with your input and output types.

To use your own serialization, you can implement the `RequestStreamHandler` interface. With this interface, Lambda passes your handler an input stream and output stream. The handler reads bytes from the input stream, writes to the output stream, and returns void. For an example of this using the Java 21 runtime, see [HandlerStream.java](#).

If you're working only with basic and generic types (i.e. `String`, `Integer`, `List`, or `Map`) in your Java function, you don't need to implement an interface. For example, if your function takes in a `Map<String, String>` input and returns a `String`, your class definition and handler signature may look like the following:

```
public class ExampleHandler {  
    public String handleRequest(Map<String, String> input, Context context) {  
        ...  
    }  
}
```

In addition, when you don't implement an interface, the [context](#) object is optional. For example, your class definition and handler signature may look like the following:

```
public class NoContextHandler {  
    public String handleRequest(Map<String, String> input) {  
        ...  
    }  
}
```

Handler naming conventions

For Lambda functions in Java, if you are implementing either the `RequestHandler` or `RequestStreamHandler` interface, your main handler method must be named `handleRequest`. Also, include the `@Override` tag above your `handleRequest` method. When you deploy your function to Lambda, specify the main handler in your function's configuration in the following format:

- `<package>.<Class>` – For example, `example.OrderHandler`.

For Lambda functions in Java that don't implement the `RequestHandler` or `RequestStreamHandler` interface, you can use any name for the handler. When you deploy your function to Lambda, specify the main handler in your function's configuration in the following format:

- `<package>.<Class>::<handler_method_name>` – For example, `example.Handler::mainHandler`.

Defining and accessing the input event object

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "orderId": "12345",
  "amount": 199.99,
  "item": "Wireless Headphones"
}
```

When working with Lambda functions in Java 17 or newer, you can define the shape of the expected input event as a Java record. In this example, we define a record within the `OrderHandler` class to represent an `Order` object:

```
public record Order(String orderId, double amount, String item) {}
```

This record matches the expected input shape. After you define your record, you can write a handler signature that takes in a JSON input that conforms to the record definition. The Java runtime automatically deserializes this JSON into a Java object. You can then access the fields of the object. For example, `event.orderId` retrieves the value of `orderId` from the original input.

Note

Java records are a feature of Java 17 runtimes and newer only. In all Java runtimes, you can use a class to represent event data. In such cases, you can use a library like [jackson](#) to deserialize JSON inputs.

Other input event types

There are many possible input events for Lambda functions in Java:

- `Integer`, `Long`, `Double`, etc. – The event is a number with no additional formatting—for example, `3.5`. The Java runtime converts the value into an object of the specified type.
- `String` – The event is a JSON string, including quotes—for example, `"My string"`. The runtime converts the value into a `String` object without quotes.
- `List<Integer>`, `List<String>`, `List<Object>`, etc. – The event is a JSON array. The runtime deserializes it into an object of the specified type or interface.
- `InputStream` – The event is any JSON type. The runtime passes a byte stream of the document to the handler without modification. You deserialize the input and write output to an output stream.
- Library type – For events sent by other AWS services, use the types in the [aws-lambda-java-events](#) library. For example, if your Lambda function is invoked by Amazon Simple Queue Service (SQS), use the `SQSEvent` object as the input.

Accessing and using the Lambda context object

The Lambda [context object](#) contains information about the invocation, function, and execution environment. In this example, the context object is of type `com.amazonaws.services.lambda.runtime.Context`, and is the second argument of the main handler function.

```
public String handleRequest(Order event, Context context) {  
    ...  
}
```

If your class implements either the [RequestHandler](#) or [RequestStreamHandler](#) interface, the context object is a required argument. Otherwise, the context object is optional. For more information about valid accepted handler signatures, see [the section called “Valid class definitions for Java handlers”](#).

If you make calls to other services using the AWS SDK, the context object is required in a few key areas. For example, to produce function logs for Amazon CloudWatch, you can use the `context.getLogger()` method to get a `LambdaLogger` object for logging. In this example, we can use the logger to log an error message if processing fails for any reason:

```
context.getLogger().log("Failed to process order: " + e.getMessage());
```

Outside of logging, you can also use the context object for function monitoring. For more information about the context object, see [the section called “Context”](#).

Using the AWS SDK for Java v2 in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the AWS SDK for Java v2.

Note

The AWS SDK for Java (v1) is in maintenance mode, and will reach end-of-support on December 31, 2025. We recommend that you use only the AWS SDK for Java v2 going forward.

To add SDK dependencies to your function, add them in your `build.gradle` for Gradle or `pom.xml` file for Maven. We recommend only adding the libraries that you need for your function. In the example code earlier, we used the `software.amazon.awssdk.services.s3` library. In Gradle, you can add this dependency by adding the following line in the dependencies section of your `build.gradle`:

```
implementation 'software.amazon.awssdk:s3:2.28.29'
```

In Maven, add the following lines in the `<dependencies>` section of your `pom.xml`:

```
<dependency>
  <groupId>software.amazon.awssdk</groupId>
  <artifactId>s3</artifactId>
  <version>2.28.29</version>
</dependency>
```

Note

This may not be the most recent version of the SDK. Choose the appropriate version of the SDK for your application.

Then, import the dependencies directly in your Java class:

```
import software.amazon.awssdk.services.s3.S3Client;
import software.amazon.awssdk.services.s3.model.PutObjectRequest;
import software.amazon.awssdk.services.s3.model.S3Exception;
```

The example code then initializes an Amazon S3 client as follows:

```
private static final S3Client S3_CLIENT = S3Client.builder().build();
```

In this example, we initialized our Amazon S3 client outside of the main handler function to avoid having to initialize it every time we invoke our function. After you initialize your SDK client, you can then use it to interact with other AWS services. The example code calls the Amazon S3 `PutObject` API as follows:

```
PutObjectRequest putObjectRequest = PutObjectRequest.builder()
    .bucket(bucketName)
    .key(key)
    .build();

// Convert the receipt content to bytes and upload to S3
S3_CLIENT.putObject(putObjectRequest,
    RequestBody.fromBytes(receiptContent.getBytes(StandardCharsets.UTF_8)));
```

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using the `System.getenv()` method. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following line of code:

```
String bucketName = System.getenv("RECEIPT_BUCKET");
if (bucketName == null || bucketName.isEmpty()) {
    throw new IllegalArgumentException("RECEIPT_BUCKET environment variable is not set");
}
```

Using global state

Lambda runs your static code and the class constructor during the [initialization phase](#) before invoking your function for the first time. Resources created during initialization stay in memory between invocations, so you can avoid having to create them every time you invoke your function.

In the example code, the S3 client initialization code is outside the main handler method. The runtime initializes the client before the function handles its first event, and the client remains available for reuse across all invocations.

Code best practices for Java Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup. For example, prefer simpler Java dependency injection (IoC) frameworks like [Dagger](#) or [Guice](#), over more complex ones like [Spring Framework](#).
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation. For functions authored in Java, avoid uploading the entire AWS SDK library as part of your deployment package. Instead, selectively depend on the modules which pick up components of the SDK you need (e.g. DynamoDB, Amazon S3 SDK modules and [Lambda core libraries](#)).

Take advantage of execution environment reuse to improve the performance of your function. Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

- **Avoid using the Java DNS cache.** Lambda functions already cache DNS responses. If you use another DNS cache, then you might experience connection timeouts.

The `java.util.logging.Logger` class can indirectly enable the JVM DNS cache. To override the default settings, set [networkaddress.cache.ttl](#) to 0 before initializing logger. Example:

```
public class MyHandler {
    // first set TTL property
    static{
        java.security.Security.setProperty("networkaddress.cache.ttl" , "0");
    }
}
```

```
}  
// then instantiate logger  
var logger = org.apache.logging.log4j.LogManager.getLogger(MyHandler.class);  
}
```

- **Reduce the time it takes Lambda to unpack deployment packages** authored in Java by putting your dependency .jar files in a separate /lib directory. This is faster than putting all your function's code in a single jar with a large number of .class files. See [Deploy Java Lambda functions with .zip or JAR file archives](#) for instructions.

Deploy Java Lambda functions with .zip or JAR file archives

Your AWS Lambda function's code consists of scripts or compiled programs and their dependencies. You use a *deployment package* to deploy your function code to Lambda. Lambda supports two types of deployment packages: container images and .zip file archives.

This page describes how to create your deployment package as a .zip file or Jar file, and then use the deployment package to deploy your function code to AWS Lambda using the AWS Command Line Interface (AWS CLI).

Important

Java 25 introduced support for Ahead-of-Time (AOT) caches. We strongly recommend not using AOT caches when deploying your functions as .zip or JAR file archives, since the caches may cause unexpected behavior when Lambda updates the managed runtime. For further information, see [Ahead-of-Time \(AOT\) and CDS caches](#).

Sections

- [Prerequisites](#)
- [Tools and libraries](#)
- [Building a deployment package with Gradle](#)
- [Using layers for dependencies](#)
- [Building a deployment package with Maven](#)
- [Uploading a deployment package with the Lambda console](#)
- [Uploading a deployment package with the AWS CLI](#)
- [Uploading a deployment package with AWS SAM](#)

Prerequisites

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

Tools and libraries

AWS provides the following libraries for Java functions. These libraries are available through [Maven Central Repository](#).

- [com.amazonaws:aws-lambda-java-core](#) (required) – Defines handler method interfaces and the context object that the runtime passes to the handler. If you define your own input types, this is the only library that you need.
- [com.amazonaws:aws-lambda-java-events](#) – Input types for events from services that invoke Lambda functions.
- [com.amazonaws:aws-lambda-java-log4j2](#) – An appender library for Apache Log4j 2 that you can use to add the request ID for the current invocation to your [function logs](#).
- [AWS SDK for Java 2.0](#) – The official AWS SDK for the Java programming language.

Add these libraries to your build definition as follows:

Gradle

```
dependencies {  
    implementation 'com.amazonaws:aws-lambda-java-core:1.2.2'  
    implementation 'com.amazonaws:aws-lambda-java-events:3.11.1'  
    runtimeOnly 'com.amazonaws:aws-lambda-java-log4j2:1.5.1'  
}
```

Maven

```
<dependencies>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-core</artifactId>  
    <version>1.2.2</version>  
  </dependency>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-events</artifactId>  
    <version>3.11.1</version>  
  </dependency>  
  <dependency>  
    <groupId>com.amazonaws</groupId>  
    <artifactId>aws-lambda-java-log4j2</artifactId>
```

```
<version>1.5.1</version>
</dependency>
</dependencies>
```

To create a deployment package, compile your function code and dependencies into a single .zip file or Java Archive (JAR) file. For Gradle, [use the Zip build type](#). For Apache Maven, [use the Maven Shade plugin](#). To upload your deployment package, use the Lambda console, the Lambda API, or AWS Serverless Application Model (AWS SAM).

Note

To keep your deployment package size small, package your function's dependencies in layers. Layers enable you to manage your dependencies independently, can be used by multiple functions, and can be shared with other accounts. For more information, see [Lambda layers](#).

Building a deployment package with Gradle

To create a deployment package with your function's code and dependencies in Gradle, use the Zip build type. Here's an example from a [complete sample build.gradle file](#):

Example build.gradle – Build task

```
task buildZip(type: Zip) {
    into('lib') {
        from(jar)
        from(configurations.runtimeClasspath)
    }
}
```

This build configuration produces a deployment package in the build/distributions directory. Within the `into('lib')` statement, the `jar` task assembles a jar archive containing your main classes into a folder named `lib`. Additionally, the `configurations.runtimeClassPath` task copies dependency libraries from the build's classpath into the same `lib` folder.

Example build.gradle – Dependencies

```
dependencies {
```

```

...
implementation 'com.amazonaws:aws-lambda-java-core:1.2.2'
implementation 'com.amazonaws:aws-lambda-java-events:3.11.1'
implementation 'org.apache.logging.log4j:log4j-api:2.17.1'
implementation 'org.apache.logging.log4j:log4j-core:2.17.1'
runtimeOnly 'org.apache.logging.log4j:log4j-slf4j18-impl:2.17.1'
runtimeOnly 'com.amazonaws:aws-lambda-java-log4j2:1.5.1'
...
}

```

Lambda loads JAR files in Unicode alphabetical order. If multiple JAR files in the `lib` directory contain the same class, the first one is used. You can use the following shell script to identify duplicate classes:

Example test-zip.sh

```

mkdir -p expanded
unzip path/to/my/function.zip -d expanded
find ./expanded/lib -name '*.jar' | xargs -n1 zipinfo -1 | grep '.*.class' | sort |
  uniq -c | sort

```

Using layers for dependencies

You can package your function's dependencies in layers to keep your deployment package small and manage dependencies independently. For more information, see [the section called “Layers”](#).

Building a deployment package with Maven

To build a deployment package with Maven, use the [Maven Shade plugin](#). The plugin creates a JAR file that contains the compiled function code and all of its dependencies.

Example pom.xml – Plugin configuration

```

<plugin>
  <groupId>org.apache.maven.plugins</groupId>
  <artifactId>maven-shade-plugin</artifactId>
  <version>3.2.2</version>
  <configuration>
    <createDependencyReducedPom>>false</createDependencyReducedPom>
  </configuration>
  <executions>
    <execution>

```

```

        <phase>package</phase>
        <goals>
            <goal>shade</goal>
        </goals>
    </execution>
</executions>
</plugin>

```

To build the deployment package, use the `mvn package` command.

```

```

This command generates a JAR file in the `target` directory.

Note

If you're working with a [multi-release JAR \(MRJAR\)](#), you must include the MRJAR (i.e. the shaded JAR produced by the Maven Shade plugin) in the `lib` directory and zip it before uploading your deployment package to Lambda. Otherwise, Lambda may not properly unpack your JAR file, causing your `MANIFEST.MF` file to be ignored.

If you use the appender library (`aws-lambda-java-log4j2`), you must also configure a transformer for the Maven Shade plugin. The transformer library combines versions of a cache file that appear in both the appender library and in Log4j.

Example pom.xml – Plugin configuration with Log4j 2 appender

```
<plugin>
  <groupId>org.apache.maven.plugins</groupId>
  <artifactId>maven-shade-plugin</artifactId>
  <version>3.2.2</version>
  <configuration>
    <createDependencyReducedPom>>false</createDependencyReducedPom>
  </configuration>
  <executions>
    <execution>
      <phase>package</phase>
      <goals>
        <goal>shade</goal>
      </goals>
      <configuration>
        <transformers>
          <transformer
implementation="com.github.edwgiz.maven_shade_plugin.log4j2_cache_transformer.PluginsCacheFile
          </transformer>
        </transformers>
      </configuration>
    </execution>
  </executions>
  <dependencies>
    <dependency>
      <groupId>com.github.edwgiz</groupId>
      <artifactId>maven-shade-plugin.log4j2-cachefile-transformer</artifactId>
      <version>2.13.0</version>
    </dependency>
  </dependencies>
</plugin>
```

Uploading a deployment package with the Lambda console

To create a new function, you must first create the function in the console, then upload your .zip or JAR file. To update an existing function, open the page for your function, then follow the same procedure to add your updated .zip or JAR file.

If your deployment package file is less than 50MB, you can create or update a function by uploading the file directly from your local machine. For .zip or JAR files greater than 50MB, you must upload your package to an Amazon S3 bucket first. For instructions on how to upload a file to an Amazon S3 bucket using the AWS Management Console, see [Getting started with Amazon S3](#). To upload files using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

You cannot change the [deployment package type](#) (.zip or container image) for an existing function. For example, you cannot convert a container image function to use a .zip file archive. You must create a new function.

To create a new function (console)

1. Open the [Functions page](#) of the Lambda console and choose **Create Function**.
2. Choose **Author from scratch**.
3. Under **Basic information**, do the following:
 - a. For **Function name**, enter the name for your function.
 - b. For **Runtime**, select the runtime you want to use.
 - c. (Optional) For **Architecture**, choose the instruction set architecture for your function. The default architecture is x86_64. Ensure that the .zip deployment package for your function is compatible with the instruction set architecture you select.
4. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing one.
5. Choose **Create function**. Lambda creates a basic 'Hello world' function using your chosen runtime.

To upload a .zip or JAR archive from your local machine (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload the .zip or JAR file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip or .jar file**.

5. To upload the .zip or JAR file, do the following:
 - a. Select **Upload**, then select your .zip or JAR file in the file chooser.
 - b. Choose **Open**.
 - c. Choose **Save**.

To upload a .zip or JAR archive from an Amazon S3 bucket (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload a new .zip or JAR file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **Amazon S3 location**.
5. Paste the Amazon S3 link URL of your .zip file and choose **Save**.

Uploading a deployment package with the AWS CLI

You can use the [AWS CLI](#) to create a new function or to update an existing one using a .zip or JAR file. Use the [create-function](#) and [update-function-code](#) commands to deploy your .zip or JAR package. If your file is smaller than 50MB, you can upload the package from a file location on your local build machine. For larger files, you must upload your .zip or JAR package from an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

If you upload your .zip or JAR file from an Amazon S3 bucket using the AWS CLI, the bucket must be located in the same AWS Region as your function.

To create a new function using a .zip or JAR file with the AWS CLI, you must specify the following:

- The name of your function (`--function-name`)
- Your function's runtime (`--runtime`)
- The Amazon Resource Name (ARN) of your function's [execution role](#) (`--role`)
- The name of the handler method in your function code (`--handler`)

You must also specify the location of your .zip or JAR file. If your .zip or JAR file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda create-function --function-name myFunction \  
--runtime java25 --handler example.handler \  
--role arn:aws:iam::123456789012:role/service-role/my-lambda-role \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--code` option as shown in the following example command. You only need to use the `S3ObjectVersion` parameter for versioned objects.

```
aws lambda create-function --function-name myFunction \  
--runtime java25 --handler example.handler \  
--role arn:aws:iam::123456789012:role/service-role/my-lambda-role \  
--code S3Bucket=amzn-s3-demo-  
bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion
```

To update an existing function using the CLI, you specify the the name of your function using the `--function-name` parameter. You must also specify the location of the .zip file you want to use to update your function code. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda update-function-code --function-name myFunction \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--s3-bucket` and `--s3-key` options as shown in the following example command. You only need to use the `--s3-object-version` parameter for versioned objects.

```
aws lambda update-function-code --function-name myFunction \  
--s3-bucket amzn-s3-demo-bucket --s3-key myFileName.zip --s3-object-version myObject  
Version
```

Uploading a deployment package with AWS SAM

You can use AWS SAM to automate deployments of your function code, configuration, and dependencies. AWS SAM is an extension of CloudFormation that provides a simplified syntax

for defining serverless applications. The following example template defines a function with a deployment package in the `build/distributions` directory that Gradle uses:

Example template.yml

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: 'AWS::Serverless-2016-10-31'
Description: An AWS Lambda application that calls the Lambda API.
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: build/distributions/java-basic.zip
      Handler: example.Handler
      Runtime: java25
      Description: Java function
      MemorySize: 512
      Timeout: 10
      # Function's execution role
      Policies:
        - AWSLambdaBasicExecutionRole
        - AWSLambda_ReadOnlyAccess
        - AWSXrayWriteOnlyAccess
        - AWSLambdaVPCLambdaAccessExecutionRole
      Tracing: Active
```

To create the function, use the `package` and `deploy` commands. These commands are customizations to the AWS CLI. They wrap other commands to upload the deployment package to Amazon S3, rewrite the template with the object URI, and update the function's code.

The following example script runs a Gradle build and uploads the deployment package that it creates. It creates an CloudFormation stack the first time you run it. If the stack already exists, the script updates it.

Example deploy.sh

```
#!/bin/bash
set -eo pipefail
aws cloudformation package --template-file template.yml --s3-bucket MY_BUCKET --output-template-file out.yml
aws cloudformation deploy --template-file out.yml --stack-name java-basic --capabilities CAPABILITY_NAMED_IAM
```

For a complete working example, see the following sample applications:

Sample Lambda applications in Java

- [example-java](#) – A Java function that demonstrates how you can use Lambda to process orders. This function illustrates how to define and deserialize a custom input event object, use the AWS SDK, and output logging.
- [java-basic](#) – A collection of minimal Java functions with unit tests and variable logging configuration.
- [java-events](#) – A collection of Java functions that contain skeleton code for how to handle events from various services such as Amazon API Gateway, Amazon SQS, and Amazon Kinesis. These functions use the latest version of the [aws-lambda-java-events](#) library (3.0.0 and newer). These examples do not require the AWS SDK as a dependency.
- [s3-java](#) – A Java function that processes notification events from Amazon S3 and uses the Java Class Library (JCL) to create thumbnails from uploaded image files.
- [layer-java](#) – A Java function that illustrates how to use a Lambda layer to package dependencies separate from your core function code.

Deploy Java Lambda functions with container images

There are three ways to build a container image for a Java Lambda function:

- [Using an AWS base image for Java](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include the [runtime interface client for Java](#) in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the [runtime interface client for Java](#) in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

Topics

- [AWS base images for Java](#)
- [Using an AWS base image for Java](#)
- [Using an alternative base image with the runtime interface client](#)

AWS base images for Java

AWS provides the following base images for Java:

Tags	Runtime	Operating system	Dockerfile	Deprecation
25	Java 25	Amazon Linux 2023	Dockerfile for Java 25 on GitHub	Jun 30, 2029
21	Java 21	Amazon Linux 2023	Dockerfile for Java 21 on GitHub	Jun 30, 2029
17	Java 17	Amazon Linux 2	Dockerfile for Java 17 on GitHub	Jun 30, 2027
11	Java 11	Amazon Linux 2	Dockerfile for Java 11 on GitHub	Jun 30, 2027
8.al2	Java 8	Amazon Linux 2	Dockerfile for Java 8 on GitHub	Jun 30, 2027

Amazon ECR repository: gallery.ecr.aws/lambda/java

The Java 21 and later base images are based on the [Amazon Linux 2023 minimal container image](#). Earlier base images use Amazon Linux 2. AL2023 provides several advantages over Amazon Linux 2, including a smaller deployment footprint and updated versions of libraries such as `glibc`.

AL2023-based images use `microdnf` (symlinked as `dnf`) as the package manager instead of `yum`, which is the default package manager in Amazon Linux 2. `microdnf` is a standalone implementation of `dnf`. For a list of packages that are included in AL2023-based images, refer to the **Minimal Container** columns in [Comparing packages installed on Amazon Linux 2023 Container Images](#). For more information about the differences between AL2023 and Amazon Linux 2, see [Introducing the Amazon Linux 2023 runtime for AWS Lambda](#) on the AWS Compute Blog.

Note

To run AL2023-based images locally, including with AWS Serverless Application Model (AWS SAM), you must use Docker version 20.10.10 or later.

Using an AWS base image for Java

Prerequisites

To complete the steps in this section, you must have the following:

- Java (for example, [Amazon Corretto](#))
- [Apache Maven](#) or [Gradle](#)
- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).

Creating an image from a base image

Maven

1. Run the following command to create a Maven project using the [archetype for Lambda](#). The following parameters are required:
 - **service** – The AWS service client to use in the Lambda function. For a list of available sources, see [aws-sdk-java-v2/services](#) on GitHub.
 - **region** – The AWS Region where you want to create the Lambda function.
 - **groupId** – The full package namespace of your application.
 - **artifactId** – Your project name. This becomes the name of the directory for your project.

In Linux and macOS, run this command:

```
mvn -B archetype:generate \
    -DarchetypeGroupId=software.amazon.awssdk \
    -DarchetypeArtifactId=archetype-lambda -Dservice=s3 -Dregion=US_WEST_2 \
    -DgroupId=com.example.myapp \
```

```
-DartifactId=myapp
```

In PowerShell, run this command:

```
mvn -B archetype:generate `
    "-DarchetypeGroupId=software.amazon.awssdk" `
    "-DarchetypeArtifactId=archetype-lambda" "-Dservice=s3" "-Dregion=US_WEST_2"
`
    "-DgroupId=com.example.myapp" `
    "-DartifactId=myapp"
```

The Maven archetype for Lambda is preconfigured to compile with Java SE 8 and includes a dependency to the AWS SDK for Java. If you create your project with a different archetype or by using another method, you must [configure the Java compiler for Maven](#) and [declare the SDK as a dependency](#).

2. Open the *myapp*/src/main/java/com/example/*myapp* directory, and find the App.java file. This is the code for the Lambda function. You can use the provided sample code for testing, or replace it with your own.
3. Navigate back to the project's root directory, and then create a new Dockerfile with the following configuration:
 - Set the FROM property to the [URI of the base image](#).
 - Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/java:21

# Copy function code and runtime dependencies from Maven layout
COPY target/classes ${LAMBDA_TASK_ROOT}
COPY target/dependency/* ${LAMBDA_TASK_ROOT}/lib/
```

```
# Set the CMD to your handler (could also be done as a parameter override
  outside of the Dockerfile)
CMD [ "com.example.myapp.App::handleRequest" ]
```

4. Compile the project and collect the runtime dependencies.

```
mvn compile dependency:copy-dependencies -DincludeScope=runtime
```

5. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-
image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

Gradle

1. Create a directory for the project, and then switch to that directory.

```
mkdir example
cd example
```

2. Run the following command to have Gradle generate a new Java application project in the example directory in your environment. For **Select build script DSL**, choose **2: Groovy**.

```
gradle init --type java-application
```

3. Open the `/example/app/src/main/java/example` directory, and find the `App.java` file. This is the code for the Lambda function. You can use the following sample code for testing, or replace it with your own.

Example App.java

```
package com.example;
import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.RequestHandler;
public class App implements RequestHandler<Object, String> {
    public String handleRequest(Object input, Context context) {
        return "Hello world!";
    }
}
```

4. Open the `build.gradle` file. If you're using the sample function code from the previous step, replace the contents of `build.gradle` with the following. If you're using your own function code, modify your `build.gradle` file as needed.

Example build.gradle (Groovy DSL)

```
plugins {
    id 'java'
}
group 'com.example'
version '1.0-SNAPSHOT'
sourceCompatibility = 1.8
repositories {
    mavenCentral()
}
dependencies {
    implementation 'com.amazonaws:aws-lambda-java-core:1.2.1'
}
jar {
    manifest {
        attributes 'Main-Class': 'com.example.App'
    }
}
```

5. The `gradle init` command from step 2 also generated a dummy test case in the `app/test` directory. For the purposes of this tutorial, skip running tests by deleting the `/test` directory.
6. Build the project.

```
gradle build
```

7. In the project's root directory (/example), create a Dockerfile with the following configuration:
 - Set the FROM property to the [URI of the base image](#).
 - Use the COPY command to copy the function code and runtime dependencies to {LAMBDA_TASK_ROOT}, a [Lambda-defined environment variable](#).
 - Set the CMD argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/lambda/java:21

# Copy function code and runtime dependencies from Gradle layout
COPY app/build/classes/java/main ${LAMBDA_TASK_ROOT}

# Set the CMD to your handler (could also be done as a parameter override
  outside of the Dockerfile)
CMD [ "com.example.App::handleRequest" ]
```

8. Build the Docker image with the [docker build](#) command. The following example names the image docker-image and gives it the test [tag](#). To make your image compatible with Lambda, you must use the --provenance=false option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the --platform linux/amd64 option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using

the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

1. Start the Docker image with the **docker run** command. In this example, `docker-image` is the image name and `test` is the tag.

```
docker run --platform linux/amd64 -p 9000:8080 docker-image:test
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

2. From a new terminal window, post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/invocations" -Method Post -Body '{"payload": "hello world!"}' -ContentType "application/json"
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

 **Note**

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
```

```
"statusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \
  --function-name hello-world \
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --publish
```

Using an alternative base image with the runtime interface client

If you use an [OS-only base image](#) or an alternative base image, you must include the runtime interface client in your image. The runtime interface client extends the [Runtime API](#), which manages the interaction between Lambda and your function code.

Install the runtime interface client for Java in your Dockerfile, or as a dependency in your project. For example, to install the runtime interface client using the Maven package manager, add the following to your `pom.xml` file:

```
<dependency>
  <groupId>com.amazonaws</groupId>
  <artifactId>aws-lambda-java-runtime-interface-client</artifactId>
  <version>2.3.2</version>
</dependency>
```

For package details, see [AWS Lambda Java Runtime Interface Client](#) in the Maven Central Repository. You can also review the runtime interface client source code in the [AWS Lambda Java Support Libraries](#) GitHub repository.

The following example demonstrates how to build a container image for Java using an [Amazon Corretto image](#). Amazon Corretto is a no-cost, multiplatform, production-ready distribution of the Open Java Development Kit (OpenJDK). The Maven project includes the runtime interface client as a dependency.

Prerequisites

To complete the steps in this section, you must have the following:

- Java (for example, [Amazon Corretto](#))
- [Apache Maven](#)
- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).

Creating an image from an alternative base image

1. Create a Maven project. The following parameters are required:

- **groupId** – The full package namespace of your application.
- **artifactId** – Your project name. This becomes the name of the directory for your project.

Linux/macOS

```
mvn -B archetype:generate \  
    -DarchetypeArtifactId=maven-archetype-quickstart \  
    -DgroupId=example \  
    -DartifactId=myapp \  
    -DinteractiveMode=false
```

PowerShell

```
mvn -B archetype:generate `   
    -DarchetypeArtifactId=maven-archetype-quickstart `
```

```
-DgroupId=example `
-DartifactId=myapp `
-DinteractiveMode=false
```

2. Open the project directory.

```
cd myapp
```

3. Open the `pom.xml` file and replace the contents with the following. This file includes the [aws-lambda-java-runtime-interface-client](#) as a dependency. Alternatively, you can install the runtime interface client in the Dockerfile. However, the simplest approach is to include the library as a dependency.

```
<project xmlns="http://maven.apache.org/POM/4.0.0" xmlns:xsi="http://
www.w3.org/2001/XMLSchema-instance"
  xsi:schemaLocation="http://maven.apache.org/POM/4.0.0 http://maven.apache.org/
maven-v4_0_0.xsd">
  <modelVersion>4.0.0</modelVersion>
  <groupId>example</groupId>
  <artifactId>hello-lambda</artifactId>
  <packaging>jar</packaging>
  <version>1.0-SNAPSHOT</version>
  <name>hello-lambda</name>
  <url>http://maven.apache.org</url>
  <properties>
    <maven.compiler.source>1.8</maven.compiler.source>
    <maven.compiler.target>1.8</maven.compiler.target>
  </properties>
  <dependencies>
    <dependency>
      <groupId>com.amazonaws</groupId>
      <artifactId>aws-lambda-java-runtime-interface-client</artifactId>
      <version>2.3.2</version>
    </dependency>
  </dependencies>
  <build>
    <plugins>
      <plugin>
        <groupId>org.apache.maven.plugins</groupId>
        <artifactId>maven-dependency-plugin</artifactId>
        <version>3.1.2</version>
        <executions>
          <execution>
```

```
        <id>copy-dependencies</id>
        <phase>package</phase>
        <goals>
            <goal>copy-dependencies</goal>
        </goals>
    </execution>
</executions>
</plugin>
</plugins>
</build>
</project>
```

4. Open the `myapp/src/main/java/com/example/myapp` directory, and find the `App.java` file. This is the code for the Lambda function. Replace the code with the following.

Example function handler

```
package example;

public class App {
    public static String sayHello() {
        return "Hello world!";
    }
}
```

5. The `mvn -B archetype:generate` command from step 1 also generated a dummy test case in the `src/test` directory. For the purposes of this tutorial, skip over running tests by deleting this entire generated `/test` directory.
6. Navigate back to the project's root directory, and then create a new Dockerfile. The following example Dockerfile uses an [Amazon Corretto image](#). Amazon Corretto is a no-cost, multiplatform, production-ready distribution of the OpenJDK.
 - Set the `FROM` property to the URI of the base image.
 - Set the `ENTRYPOINT` to the module that you want the Docker container to run when it starts. In this case, the module is the runtime interface client.
 - Set the `CMD` argument to the Lambda function handler.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-

privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
FROM public.ecr.aws/amazoncorretto/amazoncorretto:21 as base

# Configure the build environment
FROM base as build
RUN yum install -y maven
WORKDIR /src

# Cache and copy dependencies
ADD pom.xml .
RUN mvn dependency:go-offline dependency:copy-dependencies

# Compile the function
ADD . .
RUN mvn package

# Copy the function artifact and dependencies onto a clean base
FROM base
WORKDIR /function

COPY --from=build /src/target/dependency/*.jar ./
COPY --from=build /src/target/*.jar ./

# Set runtime interface client as default command for the container runtime
ENTRYPOINT [ "/usr/bin/java", "-cp", "./*",
"com.amazonaws.services.lambda.runtime.api.client.AWSLambda" ]
# Pass the name of the function handler as an argument to the runtime
CMD [ "example.App::sayHello" ]
```

7. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test the image. You can [build the emulator into your image](#) or use the following procedure to install it on your local machine.

To install and run the runtime interface emulator on your local machine

1. From your project directory, run the following command to download the runtime interface emulator (x86-64 architecture) from GitHub and install it on your local machine.

Linux/macOS

```
mkdir -p ~/.aws-lambda-rie && \  
  curl -Lo ~/.aws-lambda-rie/aws-lambda-rie https://github.com/aws/aws-lambda-  
runtime-interface-emulator/releases/latest/download/aws-lambda-rie && \  
  chmod +x ~/.aws-lambda-rie/aws-lambda-rie
```

To install the arm64 emulator, replace the GitHub repository URL in the previous command with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/  
download/aws-lambda-rie-arm64
```

PowerShell

```
$dirPath = "$HOME\.aws-lambda-rie"  
if (-not (Test-Path $dirPath)) {  
    New-Item -Path $dirPath -ItemType Directory  
}
```

```
$downloadLink = "https://github.com/aws/aws-lambda-runtime-interface-emulator/
releases/latest/download/aws-lambda-rie"
$destinationPath = "$HOME\.aws-lambda-rie\aws-lambda-rie"
Invoke-WebRequest -Uri $downloadLink -OutFile $destinationPath
```

To install the arm64 emulator, replace the `$downloadLink` with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/
download/aws-lambda-rie-arm64
```

2. Start the Docker image with the **docker run** command. Note the following:

- `docker-image` is the image name and `test` is the tag.
- `/usr/bin/java -cp './*' com.amazonaws.services.lambda.runtime.api.client.AWSLambda example.App::sayHello` is the ENTRYPOINT followed by the CMD from your Dockerfile.

Linux/macOS

```
docker run --platform linux/amd64 -d -v ~/.aws-lambda-rie:/aws-lambda -p
9000:8080 \
  --entrypoint /aws-lambda/aws-lambda-rie \
  docker-image:test \
    /usr/bin/java -cp './*'
    com.amazonaws.services.lambda.runtime.api.client.AWSLambda
    example.App::sayHello
```

PowerShell

```
docker run --platform linux/amd64 -d -v "$HOME\.aws-lambda-rie:/aws-lambda" -p
9000:8080 `
--entrypoint /aws-lambda/aws-lambda-rie `
docker-image:test `
  /usr/bin/java -cp './*'
  com.amazonaws.services.lambda.runtime.api.client.AWSLambda
  example.App::sayHello
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

3. Post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following `Invoke-WebRequest` command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/  
invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType  
"application/json"
```

4. Get the container ID.

```
docker ps
```

5. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
```

```
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-  
world",  
    "createdAt": "2023-03-09T10:39:01+00:00",  
    "imageTagMutability": "MUTABLE",  
    "imageScanningConfiguration": {  
      "scanOnPush": true  
    },  
    "encryptionConfiguration": {  
      "encryptionType": "AES256"  
    }  
  }  
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-  
world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \  
  --function-name hello-world \  
  --package-type Image \  
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{  
  "ExecutedVersion": "$LATEST",  
  "StatusCode": 200  
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --publish
```

```
--function-name hello-world \  
--image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
--publish
```

Working with layers for Java Lambda functions

Use [Lambda layers](#) to package code and dependencies that you want to reuse across multiple functions. Layers usually contain library dependencies, a [custom runtime](#), or configuration files. Creating a layer involves three general steps:

1. Package your layer content. This means creating a .zip file archive that contains the dependencies you want to use in your functions.
2. Create the layer in Lambda.
3. Add the layer to your functions.

Topics

- [Package your layer content](#)
- [Create the layer in Lambda](#)
- [Add the layer to your function](#)

Package your layer content

To create a layer, bundle your packages into a .zip file archive that meets the following requirements:

- Ensure that the Java version that Maven or Gradle refers to is the same as the Java version of the function that you intend to deploy. For example, for a Java 25 function, the `mvn -v` command should list Java 25 in the output.
- Your dependencies must be stored in the `java/lib` directory, at the root of the .zip file. For more information, see [Layer paths for each Lambda runtime](#).
- The packages in your layer must be compatible with Linux. Lambda functions run on Amazon Linux.

You can create layers that contain either third-party Java libraries or your own Java modules and packages. The following procedure uses Maven. You can also use Gradle to package your layer content.

To create a layer using Maven dependencies

1. Create an Apache Maven project with a `pom.xml` file that defines your dependencies.

The following example includes [Jackson Databind](#) for JSON processing. The `<build>` section uses the [maven-dependency-plugin](#) to create separate JAR files for each dependency instead of bundling them into a single uber-jar. If you want to create an uber-jar, use the [maven-shade-plugin](#).

Example pom.xml

```
<dependencies>
  <dependency>
    <groupId>com.fasterxml.jackson.core</groupId>
    <artifactId>jackson-databind</artifactId>
    <version>2.17.0</version>
  </dependency>
</dependencies>

<build>
  <plugins>
    <plugin>
      <groupId>org.apache.maven.plugins</groupId>
      <artifactId>maven-compiler-plugin</artifactId>
      <version>3.13.0</version>
      <configuration>
        <source>21</source>
        <target>21</target>
        <release>21</release>
      </configuration>
    </plugin>

    <plugin>
      <groupId>org.apache.maven.plugins</groupId>
      <artifactId>maven-dependency-plugin</artifactId>
      <version>3.6.1</version>
      <executions>
        <execution>
          <id>copy-dependencies</id>
          <phase>package</phase>
          <goals>
            <goal>copy-dependencies</goal>
          </goals>
        </execution>
      </executions>
    </plugin>
  </plugins>
</build>
```

```
        <configuration>
          <outputDirectory>${project.build.directory}/lib</
outputDirectory>
        </configuration>
      </execution>
    </executions>
  </plugin>
</plugins>
</build>
```

2. Build the project. This command creates all dependency JAR files in the `target/lib/` directory.

```
mvn clean package
```

3. Create the required directory structure for your layer:

```
mkdir -p java/lib
```

4. Copy the dependency JAR files to the `java/lib` directory:

```
cp target/lib/*.jar java/lib/
```

5. Zip the layer content:

Linux/macOS

```
zip -r layer.zip java/
```

PowerShell

```
Compress-Archive -Path .\java -DestinationPath .\layer.zip
```

The directory structure of your `.zip` file should look like this:

```
java/
### lib/
### jackson-databind-2.17.0.jar
### jackson-core-2.17.0.jar
### jackson-annotations-2.17.0.jar
```

Note

Make sure your .zip file includes the `java` directory at the root level with `lib` inside it. This structure ensures that Lambda can locate and import your libraries. Each dependency is kept as a separate JAR file rather than bundled into an uber-jar.

Create the layer in Lambda

You can publish your layer using either the AWS CLI or the Lambda console.

AWS CLI

Run the [publish-layer-version](#) AWS CLI command to create the Lambda layer:

```
aws lambda publish-layer-version --layer-name my-layer --zip-file fileb://layer.zip  
--compatible-runtimes java25
```

The [compatible runtimes](#) parameter is optional. When specified, Lambda uses this parameter to filter layers in the Lambda console.

Console

To create a layer (console)

1. Open the [Layers page](#) of the Lambda console.
2. Choose **Create layer**.
3. Choose **Upload a .zip file**, and then upload the .zip archive that you created earlier.
4. (Optional) For **Compatible runtimes**, choose the Java runtime that corresponds to the Java version you used to build your layer.
5. Choose **Create**.

Add the layer to your function

AWS CLI

To attach the layer to your function, run the [update-function-configuration](#) AWS CLI command. For the `--layers` parameter, use the layer ARN. The ARN must specify the version (for

example, `arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1`). For more information, see [Layers and layer versions](#).

```
aws lambda update-function-configuration --function-name my-function --cli-binary-format raw-in-base64-out --layers "arn:aws:lambda:us-east-1:123456789012:layer:my-layer:1"
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

Console

To add a layer to a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the function.
3. Scroll down to the **Layers** section, and then choose **Add a layer**.
4. Under **Choose a layer**, select **Custom layers**, and then choose your layer.

Note

If you didn't add a [compatible runtime](#) when you created the layer, your layer won't be listed here. You can specify the layer ARN instead.

5. Choose **Add**.

Customize serialization for Lambda Java functions

The Lambda [Java managed runtimes](#) support custom serialization for JSON events. Custom serialization can simplify your code and potentially improve performance.

Topics

- [When to use custom serialization](#)
- [Implementing custom serialization](#)
- [Testing custom serialization](#)

When to use custom serialization

When your Lambda function is invoked, the input event data needs to be deserialized into a Java object, and the output from your function needs to be serialized back into a format that can be returned as the function's response. The Lambda Java managed runtimes provide default serialization and deserialization capabilities that work well for handling event payloads from various AWS services, such as Amazon API Gateway and Amazon Simple Queue Service (Amazon SQS). To work with these service integration events in your function, add the [aws-java-lambda-events](#) dependency to your project. This AWS library contains Java objects representing these service integration events.

You can also use your own objects to represent the event JSON that you pass to your Lambda function. The managed runtime attempts to serialize the JSON to a new instance of your object with its default behavior. If the default serializer doesn't have the desired behavior for your use case, use custom serialization.

For example, assume that your function handler expects a `Vehicle` class as input, with the following structure:

```
public class Vehicle {  
    private String vehicleType;  
    private long vehicleId;  
}
```

However, the JSON event payload looks like this:

```
{
```

```
"vehicle-type": "car",  
"vehicleID": 123  
}
```

In this scenario, the default serialization in the managed runtime expects the JSON property names to match the camel case Java class property names (`vehicleType`, `vehicleId`). Because the property names in the JSON event aren't in camel case (`vehicle-type`, `vehicleID`), you must use custom serialization.

Implementing custom serialization

Use a [Service Provider Interface](#) to load a serializer of your choice instead of the managed runtime's default serialization logic. You can serialize your JSON event payloads directly into Java objects, using the standard `RequestHandler` interface.

To use custom serialization in your Lambda Java function

1. Add the [aws-lambda-java-core](#) library as a dependency. This library includes the [CustomPojoSerializer](#) interface, along with other interface definitions for working with Java in Lambda.
2. Create a file named `com.amazonaws.services.lambda.runtime.CustomPojoSerializer` in the `src/main/resources/META-INF/services/` directory of your project.
3. In this file, specify the fully qualified name of your custom serializer implementation, which must implement the `CustomPojoSerializer` interface. Example:

```
com.mycompany.vehicles.CustomLambdaSerializer
```

4. Implement the `CustomPojoSerializer` interface to provide your custom serialization logic.
5. Use the standard `RequestHandler` interface in your Lambda function. The managed runtime will use your custom serializer.

For more examples of how to implement custom serialization using popular libraries such as `fastJson`, `Gson`, `Moshi`, and `jackson-jr`, see the [custom-serialization](#) sample in the AWS GitHub repository.

Testing custom serialization

Test your function to make sure that your serialization and deserialization logic is working as expected. You can use the AWS Serverless Application Model Command Line Interface (AWS SAM CLI) to emulate the invocation of your Lambda payload. This can help you quickly test and iterate on your function as you introduce a custom serializer.

1. Create a file with the JSON event payload that you would like to invoke your function with then call the AWS SAM CLI.
2. Run the [sam local invoke](#) command to invoke your function locally. Example:

```
sam local invoke -e src/test/resources/event.json
```

For more information, see [Locally invoke Lambda functions with AWS SAM](#).

Customize Java runtime startup behavior for Lambda functions

This page describes settings specific to Java functions in AWS Lambda. You can use these settings to customize Java runtime startup behavior. This can reduce overall function latency and improve overall function performance, without having to modify any code.

Sections

- [Understanding the JAVA_TOOL_OPTIONS environment variable](#)
- [Log4j patch for Log4Shell](#)
- [Ahead-of-Time \(AOT\) and CDS caches](#)

Understanding the JAVA_TOOL_OPTIONS environment variable

In Java, Lambda supports the `JAVA_TOOL_OPTIONS` environment variable to set additional command-line variables in Lambda. You can use this environment variable in various ways, such as to customize tiered-compilation settings. The next example demonstrates how to use the `JAVA_TOOL_OPTIONS` environment variable for this use case.

Example: Customizing tiered compilation settings

Tiered compilation is a feature of the Java virtual machine (JVM). You can use specific tiered compilation settings to make best use of the JVM's just-in-time (JIT) compilers. Typically, the C1 compiler is optimized for fast start-up time. The C2 compiler is optimized for best overall performance, but it also uses more memory and takes a longer time to achieve it. There are 5 different levels of tiered compilation. At Level 0, the JVM interprets Java byte code. At Level 4, the JVM uses the C2 compiler to analyze profiling data collected during application startup. Over time, it monitors code usage to identify the best optimizations.

Customizing the tiered compilation level can help you tune your Java function performance. For small functions that execute quickly, setting the tiered compilation to level 1 can help improve cold start performance by having the JVM use the C1 compiler. This setting quickly produces optimized native code but it doesn't generate any profiling data and never uses the C2 compiler. For larger, computationally-intensive functions, setting tiered compilation to level 4 maximizes overall performance at the expense of additional memory consumption and additional optimization work during the first invokes after each Lambda execution environment is provisioned.

For Java 11 runtimes and below, Lambda uses the default JVM tiered compilation settings. For Java 17 and Java 21, Lambda configures the JVM to stop tiered compilation at level 1 by

default. From Java 25, Lambda still stops tiered compilation at level 1 by default, except when using SnapStart or Provisioned concurrency, in which case the default JVM settings are used. This improves performance for SnapStart and Provisioned concurrency without incurring a cold start penalty since tiered compilation is performed outside of the invoke path in these cases. To maximize this benefit, you can use priming - executing code paths during function initialization to trigger JIT before taking the SnapStart snapshot or when Provisioned Concurrency execution environments are pre-provisioned. For further information, see the blog post [Optimizing cold start performance of AWS Lambda using advanced priming strategies with SnapStart](#).

To customize tiered compilation settings (console)

1. Open the [Functions page](#) in the Lambda console.
2. Choose a Java function that you want to customize tiered compilation for.
3. Choose the **Configuration** tab, then choose **Environment variables** in the left menu.
4. Choose **Edit**.
5. Choose **Add environment variable**.
6. For the key, enter `JAVA_TOOL_OPTIONS`. For the value, enter `-XX:+TieredCompilation -XX:TieredStopAtLevel=1`.

Edit environment variables

Environment variables

You can define environment variables as key-value pairs that are accessible from your function code. These are useful to store configuration settings without the need to change function code. [Learn more](#)

Key	Value	
JAVA_TOOL_OPTIONS	-XX:+TieredCompilation -XX:TieredStopAtLevel=1	Remove

Add environment variable

► Encryption configuration

CancelSave

7. Choose **Save**.

Note

You can also use Lambda SnapStart to mitigate cold start issues. SnapStart uses cached snapshots of your execution environment to significantly improve start-up performance. For more information about SnapStart features, limitations, and supported regions, see [Improving startup performance with Lambda SnapStart](#).

Example: Customizing GC behavior using JAVA_TOOL_OPTIONS

Java 11 runtimes use the [Serial](#) garbage collector (GC) for garbage collection. By default, Java 17 runtimes also use the Serial GC. However, with Java 17 you can also use the JAVA_TOOL_OPTIONS environment variable to change the default GC. You can choose between the Parallel GC and [Shenandoah GC](#).

For example, if your workload uses more memory and multiple CPUs, consider using the Parallel GC for better performance. You can do this by appending the following to the value of your JAVA_TOOL_OPTIONS environment variable:

```
-XX:+UseParallelGC
```

If your workload has many short-lived objects, you may benefit from lower memory consumption by enabling the generational mode of the Shenandoah garbage collector introduced in Java 25. To do this, append the following to the value of your JAVA_TOOL_OPTIONS environment variable:

```
-XX:+UseShenandoahGC -XX:ShenandoahGCMode=generational
```

Log4j patch for Log4Shell

Lambda runtimes for Java 8, 11, 17, and 21 include a patch to mitigate the Log4Shell vulnerability (CVE-2021-44228) in Log4j, a popular Java logging framework. This patch incurs a cold start performance overhead. If you are using a patched version of Log4j (version 2.17.0 or later), you can disable this patch to improve cold start performance. To disable the patch, set the AWS_LAMBDA_DISABLE_CVE_2021_44228_PROTECTION environment variable to true.

Starting from Java 25, Lambda runtimes no longer include the Log4Shell patch. You must verify you are using Log4j version 2.17.0 or later.

Ahead-of-Time (AOT) and CDS caches

Starting with Java 25, the Lambda runtime includes an Ahead-of-Time (AOT) cache for the Java runtime interface client (RIC), a runtime component which actively polls for events from the Lambda Runtime API. This improves cold start performance.

AOT caches are specific to a JVM build. When Lambda updates the managed runtime, it also updates the AOT cache for the RIC. However, if you deploy your own AOT caches, these may be invalidated or result in unexpected behavior following a runtime update. We therefore strongly recommend not using AOT caches when using managed runtimes. To use AOT caches, you should deploy your functions using container images.

AOT caches cannot be used with Class Data Sharing (CDS) caches. If you deploy CDS caches in your Lambda function, then Lambda disables the AOT cache.

Using the Lambda context object to retrieve Java function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides methods and properties that provide information about the invocation, function, and execution environment.

Context methods

- `getRemainingTimeInMillis()` – Returns the number of milliseconds left before the execution times out.
- `getFunctionName()` – Returns the name of the Lambda function.
- `getFunctionVersion()` – Returns the [version](#) of the function.
- `getInvokedFunctionArn()` – Returns the Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `getMemoryLimitInMB()` – Returns the amount of memory that's allocated for the function.
- `getAwsRequestId()` – Returns the identifier of the invocation request.
- `getLogGroupName()` – Returns the log group for the function.
- `getLogStreamName()` – Returns the log stream for the function instance.
- `getIdentity()` – (mobile apps) Returns information about the Amazon Cognito identity that authorized the request.
- `getClientContext()` – (mobile apps) Returns the client context that's provided to Lambda by the client application.
- `getLogger()` – Returns the [logger object](#) for the function.

The following example shows a function that uses the context object to access the Lambda logger.

Example [Handler.java](#)

```
package example;

import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.LambdaLogger;
import com.amazonaws.services.lambda.runtime.RequestHandler;
```

```
import java.util.Map;

// Handler value: example.Handler
public class Handler implements RequestHandler<Map<String,String>, Void>{

    @Override
    public Void handleRequest(Map<String,String> event, Context context)
    {
        LambdaLogger logger = context.getLogger();
        logger.log("EVENT TYPE: " + event.getClass());
        return null;
    }
}
```

The function logs the class type of the incoming event before returning `null`.

Example log output

```
EVENT TYPE: class java.util.LinkedHashMap
```

The interface for the context object is available in the [aws-lambda-java-core](#) library. You can implement this interface to create a context class for testing. The following example shows a context class that returns dummy values for most properties and a working test logger.

Example [src/test/java/example/TestContext.java](#)

```
package example;

import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.CognitoIdentity;
import com.amazonaws.services.lambda.runtime.ClientContext;
import com.amazonaws.services.lambda.runtime.LambdaLogger;

public class TestContext implements Context{

    public TestContext() {}
    public String getAwsRequestId(){
        return new String("495b12a8-xmpl-4eca-8168-160484189f99");
    }
    public String getLogGroupName(){
        return new String("/aws/lambda/my-function");
    }
}
```

```
public String getLogStreamName(){
    return new String("2020/02/26/[$LATEST]704f8dxmlpla04097b9134246b8438f1a");
}
public String getFunctionName(){
    return new String("my-function");
}
public String getFunctionVersion(){
    return new String("$LATEST");
}
public String getInvokedFunctionArn(){
    return new String("arn:aws:lambda:us-east-2:123456789012:function:my-function");
}
public CognitoIdentity getIdentity(){
    return null;
}
public ClientContext getClientContext(){
    return null;
}
public int getRemainingTimeInMillis(){
    return 300000;
}
public int getMemoryLimitInMB(){
    return 512;
}
public LambdaLogger getLogger(){
    return new TestLogger();
}
}
```

For more information on logging, see [Log and monitor Java Lambda functions](#).

Context in sample applications

The GitHub repository for this guide includes sample applications that demonstrate the use of the context object. Each sample application includes scripts for easy deployment and cleanup, an AWS Serverless Application Model (AWS SAM) template, and supporting resources.

Sample Lambda applications in Java

- [example-java](#) – A Java function that demonstrates how you can use Lambda to process orders. This function illustrates how to define and deserialize a custom input event object, use the AWS SDK, and output logging.

- [java-basic](#) – A collection of minimal Java functions with unit tests and variable logging configuration.
- [java-events](#) – A collection of Java functions that contain skeleton code for how to handle events from various services such as Amazon API Gateway, Amazon SQS, and Amazon Kinesis. These functions use the latest version of the [aws-lambda-java-events](#) library (3.0.0 and newer). These examples do not require the AWS SDK as a dependency.
- [s3-java](#) – A Java function that processes notification events from Amazon S3 and uses the Java Class Library (JCL) to create thumbnails from uploaded image files.
- [layer-java](#) – A Java function that illustrates how to use a Lambda layer to package dependencies separate from your core function code.

Log and monitor Java Lambda functions

AWS Lambda automatically monitors Lambda functions and sends log entries to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation and other output from your function's code to the log stream. For more information about CloudWatch Logs, see [Sending Lambda function logs to CloudWatch Logs](#).

To output logs from your function code, you can use methods on [java.lang.System](#), or any logging module that writes to stdout or stderr.

Sections

Creating a function that returns logs

To output logs from your function code, you can use methods on [java.lang.System](#), or any logging module that writes to stdout or stderr. The [aws-lambda-java-core](#) library provides a logger class named `LambdaLogger` that you can access from the context object. The logger class supports multiline logs.

The following example uses the `LambdaLogger` logger provided by the context object.

Example Handler.java

```
// Handler value: example.Handler
public class Handler implements RequestHandler<Object, String>{
```

```
Gson gson = new GsonBuilder().setPrettyPrinting().create();
@Override
public String handleRequest(Object event, Context context)
{
    LambdaLogger logger = context.getLogger();
    String response = new String("SUCCESS");
    // log execution details
    logger.log("ENVIRONMENT VARIABLES: " + gson.toJson(System.getenv()));
    logger.log("CONTEXT: " + gson.toJson(context));
    // process event
    logger.log("EVENT: " + gson.toJson(event));
    return response;
}
}
```

Example log format

```
START RequestId: 6bc28136-xmpl-4365-b021-0ce6b2e64ab0 Version: $LATEST
ENVIRONMENT VARIABLES:
{
    "_HANDLER": "example.Handler",
    "AWS_EXECUTION_ENV": "AWS_Lambda_java8",
    "AWS_LAMBDA_FUNCTION_MEMORY_SIZE": "512",
    ...
}
CONTEXT:
{
    "memoryLimit": 512,
    "awsRequestId": "6bc28136-xmpl-4365-b021-0ce6b2e64ab0",
    "functionName": "java-console",
    ...
}
EVENT:
{
    "records": [
        {
            "messageId": "19dd0b57-xmpl-4ac1-bd88-01bbb068cb78",
            "receiptHandle": "MessageReceiptHandle",
            "body": "Hello from SQS!",
            ...
        }
    ]
}
```

```
END RequestId: 6bc28136-xmpl-4365-b021-0ce6b2e64ab0
REPORT RequestId: 6bc28136-xmpl-4365-b021-0ce6b2e64ab0 Duration: 198.50 ms Billed
Duration: 724 ms Memory Size: 512 MB Max Memory Used: 90 MB Init Duration: 524.75 ms
```

The Java runtime logs the START, END, and REPORT lines for each invocation. The report line provides the following details:

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

Using Lambda advanced logging controls with Java

To give you more control over how your functions' logs are captured, processed, and consumed, you can configure the following logging options for supported Java runtimes:

- **Log format** - select between plain text and structured JSON format for your function's logs
- **Log level** - for logs in JSON format, choose the detail level of the logs Lambda sends to CloudWatch, such as ERROR, DEBUG, or INFO
- **Log group** - choose the CloudWatch log group your function sends logs to

For more information about these logging options, and instructions on how to configure your function to use them, see [the section called "Configuring advanced logging controls for Lambda functions"](#).

To use the log format and log level options with your Java Lambda functions, see the guidance in the following sections.

Using structured JSON log format with Java

If you select JSON for your function's log format, Lambda will send logs output using the `LambdaLogger` class as structured JSON. Each JSON log object contains at least four key value pairs with the following keys:

- `"timestamp"` - the time the log message was generated
- `"level"` - the log level assigned to the message
- `"message"` - the contents of the log message
- `"AWSrequestId"` - the unique request ID for the function invocation

Depending on the logging method you use, log outputs from your function captured in JSON format can also contain additional key value pairs.

To assign a level to logs you create using the `LambdaLogger` logger, you need to provide a `LogLevel` argument in your logging command as shown in the following example.

Example Java logging code

```
LambdaLogger logger = context.getLogger();  
logger.log("This is a debug log", LogLevel.DEBUG);
```

This log output by this example code would be captured in CloudWatch Logs as follows:

Example JSON log record

```
{  
  "timestamp":"2023-11-01T00:21:51.358Z",  
  "level":"DEBUG",  
  "message":"This is a debug log",  
  "AWSrequestId":"93f25699-2cbf-4976-8f94-336a0aa98c6f"  
}
```

If you don't assign a level to your log output, Lambda will automatically assign it the level `INFO`.

If your code already uses another logging library to produce JSON structured logs, you don't need to make any changes. Lambda doesn't double-encode any logs that are already JSON encoded.

Even if you configure your function to use the JSON log format, your logging outputs appear in CloudWatch in the JSON structure you define.

Using log-level filtering with Java

For AWS Lambda to filter your application logs according to their log level, your function must use JSON formatted logs. You can achieve this in two ways:

- Create log outputs using the standard `LambdaLogger` and configure your function to use JSON log formatting. Lambda then filters your log outputs using the “level” key value pair in the JSON object described in [the section called “Using structured JSON log format with Java”](#). To learn how to configure your function’s log format, see [the section called “Configuring advanced logging controls for Lambda functions”](#).
- Use another logging library or method to create JSON structured logs in your code that include a “level” key value pair defining the level of the log output. You can use any logging library that can write JSON logs to `stdout` or `stderr`. For example, you can use Powertools for AWS Lambda or the Log4j2 package to generate JSON structured log outputs from your code. See [the section called “Using Powertools for AWS Lambda \(Java\) and AWS SAM for structured logging”](#) and [the section called “Implementing advanced logging with Log4j2 and SLF4J”](#) to learn more.

When you configure your function to use log-level filtering, you must select from the following options for the level of logs you want Lambda to send to CloudWatch Logs:

Log level	Standard usage
TRACE (most detail)	The most fine-grained information used to trace the path of your code's execution
DEBUG	Detailed information for system debugging
INFO	Messages that record the normal operation of your function
WARN	Messages about potential errors that may lead to unexpected behavior if unaddressed
ERROR	Messages about problems that prevent the code from performing as expected

Log level	Standard usage
FATAL (least detail)	Messages about serious errors that cause the application to stop functioning

For Lambda to filter your function's logs, you must also include a "timestamp" key value pair in your JSON log output. The time must be specified in valid [RFC 3339](#) timestamp format. If you don't supply a valid timestamp, Lambda will assign the log the level INFO and add a timestamp for you.

Lambda sends logs of the selected level and lower to CloudWatch. For example, if you configure a log level of WARN, Lambda will send logs corresponding to the WARN, ERROR, and FATAL levels.

Implementing advanced logging with Log4j2 and SLF4J

Note

AWS Lambda does not include Log4j2 in its managed runtimes or base container images. These are therefore not affected by the issues described in CVE-2021-44228, CVE-2021-45046, and CVE-2021-45105.

For cases where a customer function includes an impacted Log4j2 version, we have applied a change to the Lambda Java [managed runtimes](#) and [base container images](#) that helps to mitigate the issues in CVE-2021-44228, CVE-2021-45046, and CVE-2021-45105. As a result of this change, customers using Log4J2 may see an additional log entry, similar to "Transforming org/apache/logging/log4j/core/lookup/JndiLookup (java.net.URLClassLoader@...)". Any log strings that reference the jndi mapper in the Log4J2 output will be replaced with "Patched JndiLookup::lookup()".

Independent of this change, we strongly encourage all customers whose functions include Log4j2 to update to the latest version. Specifically, customers using the aws-lambda-java-log4j2 library in their functions should update to version 1.5.0 (or later), and redeploy their functions. This version updates the underlying Log4j2 utility dependencies to version 2.17.0 (or later). The updated aws-lambda-java-log4j2 binary is available at the [Maven repository](#) and its source code is available in [Github](#).

Lastly, take note that any libraries related to **aws-lambda-java-log4j (v1.0.0 or 1.0.1)** should **not** be used under **any** circumstance. These libraries are related to version 1.x of log4j which went end of life in 2015. The libraries are not supported, not maintained, not patched, and have known security vulnerabilities.

To customize log output, support logging during unit tests, and log AWS SDK calls, use Apache Log4j2 with SLF4J. Log4j is a logging library for Java programs that enables you to configure log levels and use appender libraries. SLF4J is a facade library that lets you change which library you use without changing your function code.

To add the request ID to your function's logs, use the appender in the [aws-lambda-java-log4j2](#) library.

Example [src/main/resources/log4j2.xml](#) – Appender configuration

```
<Configuration>
  <Appenders>
    <Lambda name="Lambda" format="${env:AWS_LAMBDA_LOG_FORMAT:-TEXT}">
      <LambdaTextFormat>
        <PatternLayout>
          <pattern>%d{yyyy-MM-dd HH:mm:ss} %X{AWSRequestId} %-5p %c{1} - %m%n </
pattern>
        </PatternLayout>
      </LambdaTextFormat>
      <LambdaJSONFormat>
        <JsonTemplateLayout eventTemplateUri="classpath:LambdaLayout.json" />
      </LambdaJSONFormat>
    </Lambda>
  </Appenders>
  <Loggers>
    <Root level="${env:AWS_LAMBDA_LOG_LEVEL:-INFO}">
      <AppenderRef ref="Lambda"/>
    </Root>
    <Logger name="software.amazon.awssdk" level="WARN" />
    <Logger name="software.amazon.awssdk.request" level="DEBUG" />
  </Loggers>
</Configuration>
```

You can decide how your Log4j2 logs are configured for either plain text or JSON outputs by specifying a layout under the `<LambdaTextFormat>` and `<LambdaJSONFormat>` tags.

In this example, in text mode, each line is prepended with the date, time, request ID, log level, and class name. In JSON mode, the `<JsonTemplateLayout>` is used with a configuration that ships together with the `aws-lambda-java-log4j2` library.

SLF4J is a facade library for logging in Java code. In your function code, you use the SLF4J logger factory to retrieve a logger with methods for log levels like `info()` and `warn()`. In your build

configuration, you include the logging library and SLF4J adapter in the classpath. By changing the libraries in the build configuration, you can change the logger type without changing your function code. SLF4J is required to capture logs from the SDK for Java.

In the following example code, the handler class uses SLF4J to retrieve a logger.

Example [src/main/java/example/HandlerS3.java](#) – Logging with SLF4J

```
package example;

import org.slf4j.Logger;
import org.slf4j.LoggerFactory;

import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.RequestHandler;
import com.amazonaws.services.lambda.runtime.events.S3Event;

import static org.apache.logging.log4j.CloseableThreadContext.put;

public class HandlerS3 implements RequestHandler<S3Event, String>{
    private static final Logger logger = LoggerFactory.getLogger(HandlerS3.class);

    @Override
    public String handleRequest(S3Event event, Context context) {
        for(var record : event.getRecords()) {
            try (var loggingCtx = put("awsRegion", record.getAwsRegion())) {
                loggingCtx.put("eventName", record.getEventName());
                loggingCtx.put("bucket", record.getS3().getBucket().getName());
                loggingCtx.put("key", record.getS3().getObject().getKey());

                logger.info("Handling s3 event");
            }
        }

        return "Ok";
    }
}
```

This code produces log outputs like the following:

Example log format

```
{
  "timestamp": "2023-11-15T16:56:00.815Z",
  "level": "INFO",
  "message": "Handling s3 event",
  "logger": "example.HandlerS3",
  "AWSRequestId": "0bced576-3936-4e5a-9dcd-db9477b77f97",
  "awsRegion": "eu-south-1",
  "bucket": "java-logging-test-input-bucket",
  "eventName": "ObjectCreated:Put",
  "key": "test-folder/"
}
```

The build configuration takes runtime dependencies on the Lambda appender and SLF4J adapter, and implementation dependencies on Log4j2.

Example build.gradle – Logging dependencies

```
dependencies {
    ...
    'com.amazonaws:aws-lambda-java-log4j2:[1.6.0,)',
    'com.amazonaws:aws-lambda-java-events:[3.11.3,)',
    'org.apache.logging.log4j:log4j-layout-template-json:[2.17.1,)',
    'org.apache.logging.log4j:log4j-slf4j2-impl:[2.19.0,)',
    ...
}
```

When you run your code locally for tests, the context object with the Lambda logger is not available, and there's no request ID for the Lambda appender to use. For example test configurations, see the sample applications in the next section.

Using other logging tools and libraries

[Powertools for AWS Lambda \(Java\)](#) is a developer toolkit to implement Serverless best practices and increase developer velocity. The [Logging utility](#) provides a Lambda optimized logger which includes additional information about function context across all your functions with output structured as JSON. Use this utility to do the following:

- Capture key fields from the Lambda context, cold start and structures logging output as JSON

- Log Lambda invocation events when instructed (disabled by default)
- Print all the logs only for a percentage of invocations via log sampling (disabled by default)
- Append additional keys to structured log at any point in time
- Use a custom log formatter (Bring Your Own Formatter) to output logs in a structure compatible with your organization's Logging RFC

Using Powertools for AWS Lambda (Java) and AWS SAM for structured logging

Follow the steps below to download, build, and deploy a sample Hello World Java application with integrated [Powertools for AWS Lambda \(Java\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- Java 11
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World Java template.

```
sam init --app-template hello-world-powertools-java --name sam-app --package-type Zip --runtime java11 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query  
'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl -X GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name sam-app
```

The log output looks like this:

```
2025/09/03/[$LATEST]851411a899b545eea2cffebe4cfbec81 2023-02-03T09:24:34.095000

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Managing log retention

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or configure a retention period after which CloudWatch automatically deletes the logs. To set up log retention, add the following to your AWS SAM template:

```
Resources:  
  HelloWorldFunction:  
    Type: AWS::Serverless::Function  
    Properties:  
      # Omitting other properties  
  
  LogGroup:  
    Type: AWS::Logs::LogGroup  
    Properties:  
      LogGroupName: !Sub "/aws/lambda/${HelloWorldFunction}"  
      RetentionInDays: 7
```

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElk0iA4N2QwNDRiOC1mMTU0LTExZTgtOGNkYS0yOTc0YzVlNGZiMjEgVmVyc2l1vb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB
```

The `base64` utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"//g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
{
  "events": [
    {
      "timestamp": 1559763003171,
      "message": "START RequestId: 4ce9340a-b765-490f-ad8a-02ab3415e2bf Version:

}

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Sample logging code

The GitHub repository for this guide includes sample applications that demonstrate the use of various logging configurations. Each sample application includes scripts for easy deployment and cleanup, an AWS SAM template, and supporting resources.

Sample Lambda applications in Java

- [example-java](#) – A Java function that demonstrates how you can use Lambda to process orders. This function illustrates how to define and deserialize a custom input event object, use the AWS SDK, and output logging.

- [java-basic](#) – A collection of minimal Java functions with unit tests and variable logging configuration.
- [java-events](#) – A collection of Java functions that contain skeleton code for how to handle events from various services such as Amazon API Gateway, Amazon SQS, and Amazon Kinesis. These functions use the latest version of the [aws-lambda-java-events](#) library (3.0.0 and newer). These examples do not require the AWS SDK as a dependency.
- [s3-java](#) – A Java function that processes notification events from Amazon S3 and uses the Java Class Library (JCL) to create thumbnails from uploaded image files.
- [layer-java](#) – A Java function that illustrates how to use a Lambda layer to package dependencies separate from your core function code.

The `java-basic` sample application shows a minimal logging configuration that supports logging tests. The handler code uses the `LambdaLogger` logger provided by the context object. For tests, the application uses a custom `TestLogger` class that implements the `LambdaLogger` interface with a Log4j2 logger. It uses SLF4J as a facade for compatibility with the AWS SDK. Logging libraries are excluded from build output to keep the deployment package small.

Instrumenting Java code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of two SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for Java](#) – An SDK for generating and sending trace data to X-Ray.
- [Powertools for AWS Lambda \(Java\)](#) – A developer toolkit to implement Serverless best practices and increase developer velocity.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

- [X-Ray tracing in sample applications \(X-Ray SDK\)](#)

Using Powertools for AWS Lambda (Java) and AWS SAM for tracing

Follow the steps below to download, build, and deploy a sample Hello World Java application with integrated [Powertools for AWS Lambda \(Java\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- Java 11 or later
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World Java template.

```
sam init --app-template hello-world-powertools-java --name sam-app --package-type Zip --runtime java11 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

- Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

 **Note**

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

- Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query  
'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

- Invoke the API endpoint:

```
curl -X GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

- To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

```
New XRay Service Graph  
Start time: 2025-02-03 14:31:48+01:00  
End time: 2025-02-03 14:31:48+01:00  
Reference Id: 0 - (Root) AWS::Lambda - sam-app-HelloWorldFunction-y9Iu1FLJJBGD -

```

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Using Powertools for AWS Lambda (Java) and the AWS CDK for tracing

Follow the steps below to download, build, and deploy a sample Hello World Java application with integrated [Powertools for AWS Lambda \(Java\)](#) modules using the AWS CDK. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- Java 11 or later
- [AWS CLI version 2](#)
- [AWS CDK version 2](#)

- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS CDK application

1. Create a project directory for your new application.

```
mkdir hello-world
cd hello-world
```

2. Initialize the app.

```
cdk init app --language java
```

3. Create a maven project with the following command:

```
mkdir app
cd app
mvn archetype:generate -DgroupId=helloworld -DartifactId=Function -
DarchetypeArtifactId=maven-archetype-quickstart -DinteractiveMode=false
```

4. Open pom.xml in the hello-world\app\Function directory and replace the existing code with the following code that includes dependencies and maven plugins for Powertools.

```
<project xmlns="http://maven.apache.org/POM/4.0.0" xmlns:xsi="http://
www.w3.org/2001/XMLSchema-instance"
  xsi:schemaLocation="http://maven.apache.org/POM/4.0.0 http://maven.apache.org/
maven-v4_0_0.xsd">
  <modelVersion>4.0.0</modelVersion>
  <groupId>helloworld</groupId>
  <artifactId>Function</artifactId>
  <packaging>jar</packaging>
  <version>1.0-SNAPSHOT</version>
  <name>Function</name>
  <url>http://maven.apache.org</url>
  <properties>
    <maven.compiler.source>11</maven.compiler.source>
    <maven.compiler.target>11</maven.compiler.target>
    <log4j.version>2.17.2</log4j.version>
  </properties>
  <dependencies>
    <dependency>
```

```

        <groupId>junit</groupId>
        <artifactId>junit</artifactId>
        <version>3.8.1</version>
        <scope>test</scope>
    </dependency>
    <dependency>
        <groupId>software.amazon.lambda</groupId>
        <artifactId>powertools-tracing</artifactId>
        <version>1.3.0</version>
    </dependency>
    <dependency>
        <groupId>software.amazon.lambda</groupId>
        <artifactId>powertools-metrics</artifactId>
        <version>1.3.0</version>
    </dependency>
    <dependency>
        <groupId>software.amazon.lambda</groupId>
        <artifactId>powertools-logging</artifactId>
        <version>1.3.0</version>
    </dependency>
    <dependency>
        <groupId>com.amazonaws</groupId>

  <execution>
    <goals>
      <goal>compile</goal>
    </goals>
  </execution>
</executions>
</plugin>
<plugin>
  <groupId>org.apache.maven.plugins</groupId>
  <artifactId>maven-shade-plugin</artifactId>
  <version>3.4.1</version>
  <executions>
    <execution>
      <phase>package</phase>
      <goals>
        <goal>shade</goal>
      </goals>
      <configuration>
        <transformers>
          <transformer
implementation="com.github.edwgiz.maven_shade_plugin.log4j2_cache_transformer.PluginsCache
          </transformer>
        </transformers>
        <createDependencyReducedPom>>false</
createDependencyReducedPom>
        <finalName>function</finalName>

      </configuration>
    </execution>
  </executions>

```

```

        <dependencies>
            <dependency>
                <groupId>com.github.edwgiz</groupId>
                <artifactId>maven-shade-plugin.log4j2-cachefile-
transformer</artifactId>
                <version>2.15</version>
            </dependency>
        </dependencies>
    </plugin>
</plugins>
</build>
</project>

```

5. Create the `hello-world\app\src\main\resource` directory and create `log4j.xml` for the log configuration.

```

mkdir -p src/main/resource
cd src/main/resource
touch log4j.xml

```

6. Open `log4j.xml` and add the following code.

```

<?xml version="1.0" encoding="UTF-8"?>
<Configuration>
    <Appenders>
        <Console name="JsonAppender" target="SYSTEM_OUT">
            <JsonTemplateLayout
eventTemplateUri="classpath:LambdaJsonLayout.json" />
        </Console>
    </Appenders>
    <Loggers>
        <Logger name="JsonLogger" level="INFO" additivity="false">
            <AppenderRef ref="JsonAppender"/>
        </Logger>
        <Root level="info">
            <AppenderRef ref="JsonAppender"/>
        </Root>
    </Loggers>
</Configuration>

```

7. Open `App.java` from the `hello-world\app\Function\src\main\java\helloworld` directory and replace the existing code with the following code. This is the code for the Lambda function.

```

package helloworld;

import java.io.BufferedReader;
import java.io.IOException;
import java.io.InputStreamReader;
import java.net.URL;
import java.util.HashMap;
import java.util.Map;
import java.util.stream.Collectors;

import com.amazonaws.services.lambda.runtime.Context;
import com.amazonaws.services.lambda.runtime.RequestHandler;
import com.amazonaws.services.lambda.runtime.events.APIGatewayProxyRequestEvent;
import com.amazonaws.services.lambda.runtime.events.APIGatewayProxyResponseEvent;
import org.apache.logging.log4j.LogManager;
import org.apache.logging.log4j.Logger;
import software.amazon.lambda.powertools.logging.Logging;
import software.amazon.lambda.powertools.metrics.Metrics;
import software.amazon.lambda.powertools.tracing.CaptureMode;
import software.amazon.lambda.powertools.tracing.Tracing;

import static software.amazon.lambda.powertools.tracing.CaptureMode.*;

/**
 * Handler for requests to Lambda function.
 */
public class App implements RequestHandler<APIGatewayProxyRequestEvent,
    APIGatewayProxyResponseEvent> {
    Logger log = LogManager.getLogger(App.class);

    @Logging(logEvent = true)
    @Tracing(captureMode = DISABLED)
    @Metrics(captureColdStart = true)
    public APIGatewayProxyResponseEvent handleRequest(final
    APIGatewayProxyRequestEvent input, final Context context) {
        Map<String, String> headers = new HashMap<>();
        headers.put("Content-Type", "application/json");
        headers.put("X-Custom-Header", "application/json");

        APIGatewayProxyResponseEvent response = new APIGatewayProxyResponseEvent()
            .withHeaders(headers);
        try {

```

```

        final String pageContents = this.getPageContents("https://
checkip.amazonaws.com");
        String output = String.format("{ \"message\": \"hello world\",
        \"location\": \"%s\" }", pageContents);

        return response
            .withStatusCode(200)
            .withBody(output);
    } catch (IOException e) {
        return response
            .withBody("{}")
            .withStatusCode(500);
    }
}
@Tracing(namespace = "getPageContents")
private String getPageContents(String address) throws IOException {
    log.info("Retrieving {}", address);
    URL url = new URL(address);
    try (BufferedReader br = new BufferedReader(new
InputStreamReader(url.openStream())) {
        return br.lines().collect(Collectors.joining(System.lineSeparator()));
    }
}
}
}

```

8. Open `HelloWorldStack.java` from the `hello-world\src\main\java\com\myorg` directory and replace the existing code with the following code. This code uses [Lambda Constructor](#) and the [ApiGatewayv2 Constructor](#) to create a REST API and a Lambda function.

```

package com.myorg;

import software.amazon.awscdk.*;
import software.amazon.awscdk.services.apigatewayv2.alpha.*;
import
    software.amazon.awscdk.services.apigatewayv2.integrations.alpha.HttpLambdaIntegration;
import
    software.amazon.awscdk.services.apigatewayv2.integrations.alpha.HttpLambdaIntegrationProps;
import software.amazon.awscdk.services.lambda.Code;
import software.amazon.awscdk.services.lambda.Function;
import software.amazon.awscdk.services.lambda.FunctionProps;
import software.amazon.awscdk.services.lambda.Runtime;
import software.amazon.awscdk.services.lambda.Tracing;
import software.amazon.awscdk.services.logs.RetentionDays;

```

```

import software.amazon.awscdk.services.s3.assets.AssetOptions;
import software.constructs.Construct;

import java.util.Arrays;
import java.util.List;

import static java.util.Collections.singletonList;

public class HelloWorldStack extends Stack {
    public HelloWorldStack(final Construct scope, final String id) {
        this(scope, id, null);
    }

    public HelloWorldStack(final Construct scope, final String id, final StackProps
props) {
        super(scope, id, props);

        List<String> functionPackagingInstructions = Arrays.asList(
            "/bin/sh",
            "-c",
            "cd Function " +
                "&& mvn clean install " +
                "&& cp /asset-input/Function/target/function.jar /asset-
output/"
        );
        BundlingOptions.Builder builderOptions = BundlingOptions.builder()
            .command(functionPackagingInstructions)
            .image(Runtime.JAVA_11.getBundlingImage())
            .volumes(singletonList(
                // Mount local .m2 repo to avoid download all the
dependencies again inside the container
                DockerVolume.builder()
                    .hostPath(System.getProperty("user.home") +
"/.m2/")
                    .containerPath("/root/.m2/")
                    .build()
            ))
            .user("root")
            .outputType(ARCHIVED);

        Function function = new Function(this, "Function", FunctionProps.builder()
            .runtime(Runtime.JAVA_11)
            .code(Code.fromAsset("app", AssetOptions.builder()

```

```

        .bundling(builderOptions
            .command(functionPackagingInstructions)
            .build())
        .build()))
    .handler("helloworld.App::handleRequest")
    .memorySize(1024)
    .tracing(Tracing.ACTIVE)
    .timeout(Duration.seconds(10))
    .logRetention(RetentionDays.ONE_WEEK)
    .build());

    HttpApi httpApi = new HttpApi(this, "sample-api", HttpApiProps.builder()
        .apiName("sample-api")
        .build());

    httpApi.addRoutes(AddRoutesOptions.builder()
        .path("/")
        .methods(singletonList(HttpMethod.GET))
        .integration(new HttpLambdaIntegration("function", function,
            HttpLambdaIntegrationProps.builder()
                .payloadFormatVersion(PayloadFormatVersion.VERSION_2_0)
                .build()))
        .build());

    new CfnOutput(this, "HttpApi", CfnOutputProps.builder()
        .description("Url for Http Api")
        .value(httpApi.getApiEndpoint())
        .build());
}
}

```

9. Open `pom.xml` from the `hello-world` directory and replace the existing code with the following code.

```

<?xml version="1.0" encoding="UTF-8"?>
<project xsi:schemaLocation="http://maven.apache.org/POM/4.0.0 http://
maven.apache.org/xsd/maven-4.0.0.xsd"
    xmlns="http://maven.apache.org/POM/4.0.0" xmlns:xsi="http://
www.w3.org/2001/XMLSchema-instance">
    <modelVersion>4.0.0</modelVersion>

    <groupId>com.myorg</groupId>
    <artifactId>hello-world</artifactId>

```

```

<version>0.1</version>

<properties>
  <project.build.sourceEncoding>UTF-8</project.build.sourceEncoding>
  <cdk.version>2.70.0</cdk.version>
  <constructs.version>[10.0.0,11.0.0)</constructs.version>
  <junit.version>5.7.1</junit.version>
</properties>

<build>
  <plugins>
    <plugin>
      <groupId>org.apache.maven.plugins</groupId>
      <artifactId>maven-compiler-plugin</artifactId>
      <version>3.8.1</version>
      <configuration>
        <source>1.8</source>
        <target>1.8</target>
      </configuration>
    </plugin>

    <plugin>
      <groupId>org.codehaus.mojo</groupId>
      <artifactId>exec-maven-plugin</artifactId>
      <version>3.0.0</version>
      <configuration>
        <mainClass>com.myorg.HelloWorldApp</mainClass>
      </configuration>
    </plugin>
  </plugins>
</build>

<dependencies>
  <!-- AWS Cloud Development Kit -->
  <dependency>
    <groupId>software.amazon.awscdk</groupId>
    <artifactId>aws-cdk-lib</artifactId>
    <version>${cdk.version}</version>
  </dependency>
  <dependency>
    <groupId>software.constructs</groupId>
    <artifactId>constructs</artifactId>
    <version>${constructs.version}</version>
  </dependency>

```

```
<dependency>
  <groupId>org.junit.jupiter</groupId>
  <artifactId>junit-jupiter</artifactId>
  <version>${junit.version}</version>
  <scope>test</scope>
</dependency>
<dependency>
  <groupId>software.amazon.awscdk</groupId>
  <artifactId>apigatewayv2-alpha</artifactId>
  <version>${cdk.version}-alpha.0</version>
</dependency>
<dependency>
  <groupId>software.amazon.awscdk</groupId>
  <artifactId>apigatewayv2-integrations-alpha</artifactId>
  <version>${cdk.version}-alpha.0</version>
</dependency>
</dependencies>
</project>
```

10. Make sure you're in the `hello-world` directory and deploy your application.

```
cdk deploy
```

11. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name HelloWorldStack --query
'Stacks[0].Outputs[?OutputKey=='HttpApi'].OutputValue' --output text
```

12. Invoke the API endpoint:

```
curl -X GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message": "hello world"}
```

13. To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

New XRay Service Graph

Start time: 2025-02-03 14:59:50+00:00

End time: 2025-02-03 14:59:50+00:00

```
cdk destroy
```

Using ADOT to instrument your Java functions

ADOT provides fully managed Lambda [layers](#) that package everything you need to collect telemetry data using the OTel SDK. By consuming this layer, you can instrument your Lambda functions without having to modify any function code. You can also configure your layer to do custom initialization of OTel. For more information, see [Custom configuration for the ADOT Collector on Lambda](#) in the ADOT documentation.

For Java runtimes, you can choose between two layers to consume:

- **AWS managed Lambda layer for ADOT Java (Auto-instrumentation Agent)** – This layer automatically transforms your function code at startup to collect tracing data. For detailed instructions on how to consume this layer together with the ADOT Java agent, see [AWS Distro for OpenTelemetry Lambda Support for Java \(Auto-instrumentation Agent\)](#) in the ADOT documentation.
- **AWS managed Lambda layer for ADOT Java** – This layer also provides built-in instrumentation for Lambda functions, but it requires a few manual code changes to initialize the OTel SDK. For detailed instructions on how to consume this layer, see [AWS Distro for OpenTelemetry Lambda Support for Java](#) in the ADOT documentation.

Using the X-Ray SDK to instrument your Java functions

To record data about calls that your function makes to other resources and services in your application, you can add the X-Ray SDK for Java to your build configuration. The following example shows a Gradle build configuration that includes the libraries that activate automatic instrumentation of AWS SDK for Java 2.x clients.

Example [build.gradle](#) – Tracing dependencies

```
dependencies {  
    implementation platform('software.amazon.awssdk:bom:2.16.1')  
    implementation platform('com.amazonaws:aws-xray-recorder-sdk-bom:2.11.0')  
    ...  
    implementation 'com.amazonaws:aws-xray-recorder-sdk-core'  
    implementation 'com.amazonaws:aws-xray-recorder-sdk-aws-sdk'  
    implementation 'com.amazonaws:aws-xray-recorder-sdk-aws-sdk-v2-instrumentor'  
    ...  
}
```

After you add the correct dependencies and make the necessary code changes, activate tracing in your function's configuration via the Lambda console or the API.

Activating tracing with the Lambda console

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Monitoring and operations tools**.
4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.
6. Choose **Save**.

Activating tracing with the Lambda API

Configure tracing on your Lambda function with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Activating tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in an CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Lambda::Function
    Properties:
      TracingConfig:
        Mode: Active
      ...
```

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

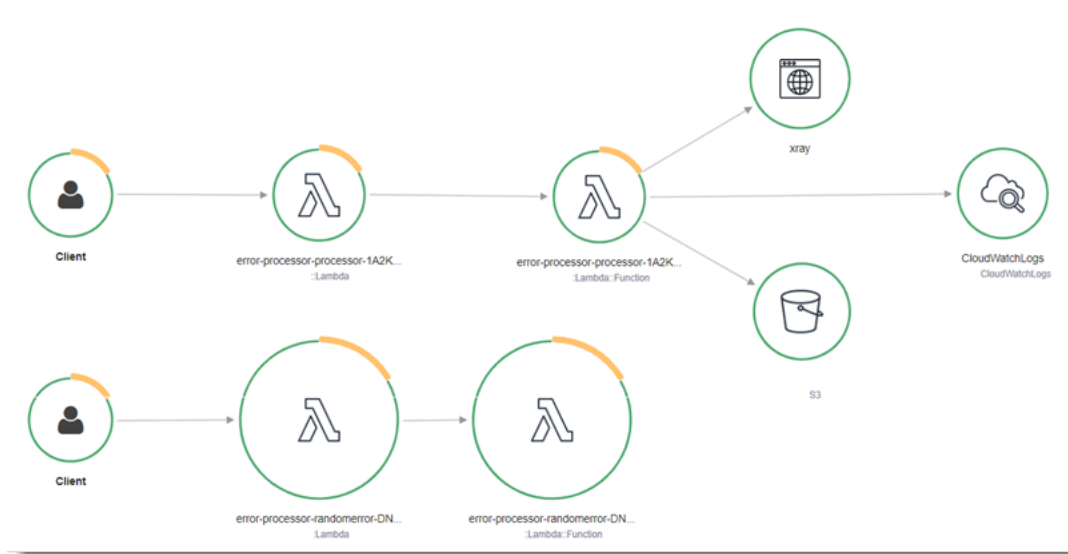

Example [template.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      Tracing: Active
      ...
```

Interpreting an X-Ray trace

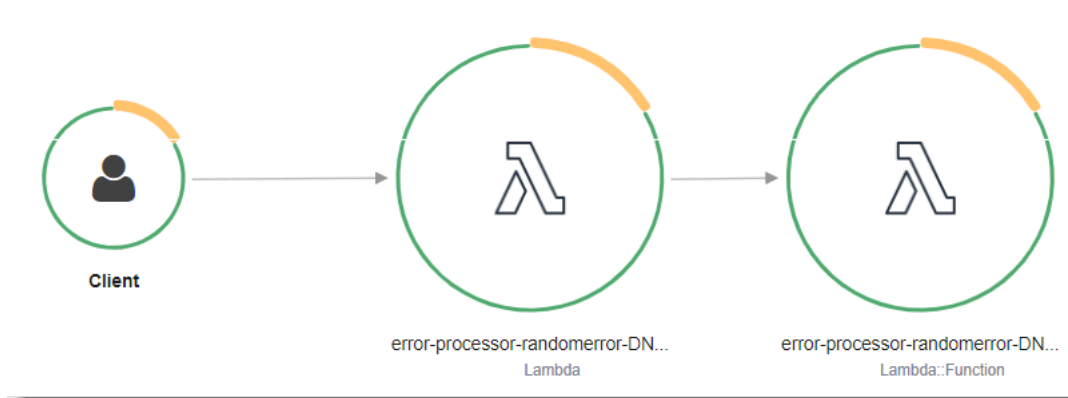

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

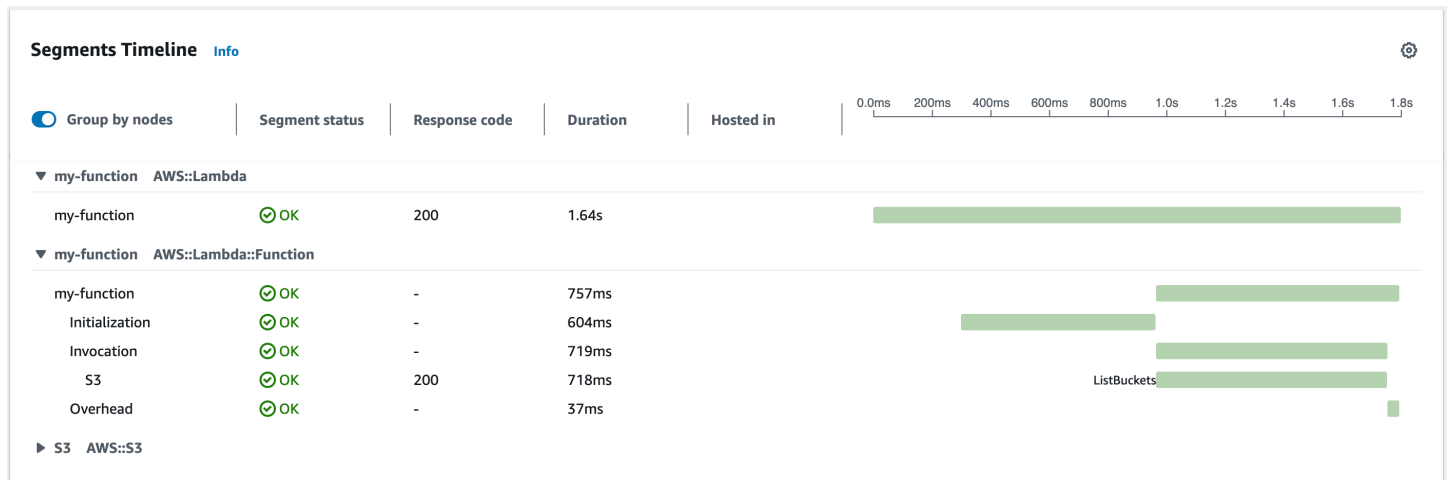

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an `Invocation` subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called "Understanding X-Ray traces"](#).

Note

[Lambda SnapStart](#) functions also include a Restore subsegment. The Restore subsegment shows the time it takes for Lambda to restore a snapshot, load the runtime, and run any after-restore [runtime hooks](#). The process of restoring snapshots can include time spent on activities outside the MicroVM. This time is reported in the Restore subsegment. You aren't charged for the time spent outside the microVM to restore a snapshot.

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see [AWS X-Ray SDK for Java](#) in the *AWS X-Ray Developer Guide*.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

Storing runtime dependencies in a layer (X-Ray SDK)

If you use the X-Ray SDK to instrument AWS SDK clients your function code, your deployment package can become quite large. To avoid uploading runtime dependencies every time you update your function code, package the X-Ray SDK in a [Lambda layer](#).

The following example shows an `AWS::Serverless::LayerVersion` resource that stores the AWS SDK for Java and X-Ray SDK for Java.

Example [template.yml](#) – Dependencies layer

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      CodeUri: build/distributions/blank-java.zip
      Tracing: Active
      Layers:
```

```
- !Ref libs
...
libs:
  Type: AWS::Serverless::LayerVersion
  Properties:
    LayerName: blank-java-lib
    Description: Dependencies for the blank-java sample app.
    ContentUri: build/blank-java-lib.zip
    CompatibleRuntimes:
      - java25
```

With this configuration, you update the library layer only if you change your runtime dependencies. Since the function deployment package contains only your code, this can help reduce upload times.

Creating a layer for dependencies requires build configuration changes to generate the layer archive prior to deployment. For a working example, see the [java-basic](#) sample application on GitHub.

X-Ray tracing in sample applications (X-Ray SDK)

The GitHub repository for this guide includes sample applications that demonstrate the use of X-Ray tracing. Each sample application includes scripts for easy deployment and cleanup, an AWS SAM template, and supporting resources.

Sample Lambda applications in Java

- [example-java](#) – A Java function that demonstrates how you can use Lambda to process orders. This function illustrates how to define and deserialize a custom input event object, use the AWS SDK, and output logging.
- [java-basic](#) – A collection of minimal Java functions with unit tests and variable logging configuration.
- [java-events](#) – A collection of Java functions that contain skeleton code for how to handle events from various services such as Amazon API Gateway, Amazon SQS, and Amazon Kinesis. These functions use the latest version of the [aws-lambda-java-events](#) library (3.0.0 and newer). These examples do not require the AWS SDK as a dependency.
- [s3-java](#) – A Java function that processes notification events from Amazon S3 and uses the Java Class Library (JCL) to create thumbnails from uploaded image files.
- [layer-java](#) – A Java function that illustrates how to use a Lambda layer to package dependencies separate from your core function code.

All of the sample applications have active tracing enabled for Lambda functions. For example, the `s3-java` application shows automatic instrumentation of AWS SDK for Java 2.x clients, segment management for tests, custom subsegments, and the use of Lambda layers to store runtime dependencies.

Java sample applications for AWS Lambda

The GitHub repository for this guide provides sample applications that demonstrate the use of Java in AWS Lambda. Each sample application includes scripts for easy deployment and cleanup, an CloudFormation template, and supporting resources.

Sample Lambda applications in Java

- [example-java](#) – A Java function that demonstrates how you can use Lambda to process orders. This function illustrates how to define and deserialize a custom input event object, use the AWS SDK, and output logging.
- [java-basic](#) – A collection of minimal Java functions with unit tests and variable logging configuration.
- [java-events](#) – A collection of Java functions that contain skeleton code for how to handle events from various services such as Amazon API Gateway, Amazon SQS, and Amazon Kinesis. These functions use the latest version of the [aws-lambda-java-events](#) library (3.0.0 and newer). These examples do not require the AWS SDK as a dependency.
- [s3-java](#) – A Java function that processes notification events from Amazon S3 and uses the Java Class Library (JCL) to create thumbnails from uploaded image files.
- [layer-java](#) – A Java function that illustrates how to use a Lambda layer to package dependencies separate from your core function code.

Running popular Java frameworks on Lambda

- [spring-cloud-function-samples](#) – An example from Spring that shows how to use the [Spring Cloud Function](#) framework to create AWS Lambda functions.
- [Serverless Spring Boot Application Demo](#) – An example that shows how to set up a typical Spring Boot application in a managed Java runtime with and without SnapStart, or as a GraalVM native image with a custom runtime.
- [Serverless Micronaut Application Demo](#) – An example that shows how to use Micronaut in a managed Java runtime with and without SnapStart, or as a GraalVM native image with a custom runtime. Learn more in the [Micronaut/Lambda guides](#).
- [Serverless Quarkus Application Demo](#) – An example that shows how to use Quarkus in a managed Java runtime with and without SnapStart, or as a GraalVM native image with a custom runtime. Learn more in the [Quarkus/Lambda guide](#) and [Quarkus/SnapStart guide](#).

If you're new to Lambda functions in Java, start with the `java-basic` examples. To get started with Lambda event sources, see the `java-events` examples. Both of these example sets show the use of Lambda's Java libraries, environment variables, the AWS SDK, and the AWS X-Ray SDK. These examples require minimal setup and you can deploy them from the command line in less than a minute.

Building Lambda functions with Go

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only runtime](#) (the provided runtime family) to deploy Go functions to Lambda.

Topics

- [Go runtime support](#)
- [Tools and libraries](#)
- [Define Lambda function handlers in Go](#)
- [Using the Lambda context object to retrieve Go function information](#)
- [Deploy Go Lambda functions with .zip file archives](#)
- [Deploy Go Lambda functions with container images](#)
- [Working with layers for Go Lambda functions](#)
- [Log and monitor Go Lambda functions](#)
- [Instrumenting Go code in AWS Lambda](#)

Go runtime support

The Go 1.x managed runtime for Lambda is [deprecated](#). If you have functions that use the Go 1.x runtime, you must migrate your functions to `provided.al2023` or `provided.al2`. The `provided.al2023` and `provided.al2` runtimes offer several advantages over `go1.x`, including support for the arm64 architecture (AWS Graviton2 processors), smaller binaries, and slightly faster invoke times.

No code changes are required for this migration. The only required changes relate to how you build your deployment package and which runtime you use to create your function. For more information, see [Migrating AWS Lambda functions from the Go1.x runtime to the custom runtime on Amazon Linux 2](#) on the *AWS Compute Blog*.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
OS-only Runtime	provided.al2023	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029
OS-only Runtime	provided.al2	Amazon Linux 2	Jul 31, 2026	Aug 31, 2026	Sep 30, 2026

Tools and libraries

Lambda provides the following tools and libraries for the Go runtime:

- [AWS SDK for Go v2](#): The official AWS SDK for the Go programming language.
- github.com/aws/aws-lambda-go/lambda: The implementation of the Lambda programming model for Go. This package is used by AWS Lambda to invoke your [handler](#).
- github.com/aws/aws-lambda-go/lambdacontext: Helpers for accessing context information from the [context object](#).
- github.com/aws/aws-lambda-go/events: This library provides type definitions for common event source integrations.
- github.com/aws/aws-lambda-go/cmd/build-lambda-zip: This tool can be used to create a .zip file archive on Windows.

For more information, see [aws-lambda-go](#) on GitHub.

Lambda provides the following sample applications for the Go runtime:

Sample Lambda applications in Go

- [go-al2](#) – A hello world function that returns the public IP address. This app uses the `provided.al2` custom runtime.
- [blank-go](#) – A Go function that shows the use of Lambda's Go libraries, logging, environment variables, and the AWS SDK. This app uses the `go1.x` runtime.

Define Lambda function handlers in Go

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in Go, including project setup, naming conventions, and best practices. This page also includes an example of a Go Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (Amazon S3) bucket. For information about how to deploy your function after writing it, see [the section called “Deploy .zip file archives”](#) or [the section called “Deploy container images”](#).

- [Accessing and using the Lambda context object](#)
- [Valid handler signatures for Go handlers](#)
- [Using the AWS SDK for Go v2 in your handler](#)
- [Accessing environment variables](#)
- [Using global state](#)
- [Code best practices for Go Lambda functions](#)

Setting up your Go handler project

A Lambda function written in [Go](#) is authored as a Go executable. You can initialize a Go Lambda function project the same way you initialize any other Go project using the following `go mod init` command:

```
go mod init example-go
```

Here, `example-go` is the module name. You can replace this with anything. This command initializes your project and generates the `go.mod` file that lists your project's dependencies.

Use the `go get` command to add any external dependencies to your project. For example, for all Lambda functions in Go, you must include the github.com/aws/aws-lambda-go/lambda package, which implements the Lambda programming model for Go. Include this package with the following `go get` command:

```
go get github.com/aws/aws-lambda-go
```

Your function code should live in a Go file. In the following example, we name this file `main.go`. In this file, you implement your core function logic in a handler method, as well as a `main()` function that calls this handler.

Example Go Lambda function code

The following example Go Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket.

Example `main.go` Lambda function

```
package main

import (
    "context"
    "encoding/json"
    "fmt"
    "log"
    "os"
    "strings"

    "github.com/aws/aws-lambda-go/lambda"
    "github.com/aws/aws-sdk-go-v2/config"
    "github.com/aws/aws-sdk-go-v2/service/s3"
)

type Order struct {
    OrderID string `json:"order_id"`
    Amount  float64 `json:"amount"`
    Item    string  `json:"item"`
}

var (
    s3Client *s3.Client
)
```

```
func init() {
    // Initialize the S3 client outside of the handler, during the init phase
    cfg, err := config.LoadDefaultConfig(context.TODO())
    if err != nil {
        log.Fatalf("unable to load SDK config, %v", err)
    }

    s3Client = s3.NewFromConfig(cfg)
}

func uploadReceiptToS3(ctx context.Context, bucketName, key, receiptContent string)
    error {
    _, err := s3Client.PutObject(ctx, &s3.PutObjectInput{
        Bucket: &bucketName,
        Key:     &key,
        Body:    strings.NewReader(receiptContent),
    })
    if err != nil {
        log.Printf("Failed to upload receipt to S3: %v", err)
        return err
    }
    return nil
}

func handleRequest(ctx context.Context, event json.RawMessage) error {
    // Parse the input event
    var order Order
    if err := json.Unmarshal(event, &order); err != nil {
        log.Printf("Failed to unmarshal event: %v", err)
        return err
    }

    // Access environment variables
    bucketName := os.Getenv("RECEIPT_BUCKET")
    if bucketName == "" {
        log.Printf("RECEIPT_BUCKET environment variable is not set")
        return fmt.Errorf("missing required environment variable RECEIPT_BUCKET")
    }

    // Create the receipt content and key destination
    receiptContent := fmt.Sprintf("OrderID: %s\nAmount: $%.2f\nItem: %s",
        order.OrderID, order.Amount, order.Item)
    key := "receipts/" + order.OrderID + ".txt"
```

```
// Upload the receipt to S3 using the helper method
if err := uploadReceiptToS3(ctx, bucketName, key, receiptContent); err != nil {
    return err
}

log.Printf("Successfully processed order %s and stored receipt in S3 bucket %s",
order.OrderID, bucketName)
return nil
}

func main() {
    lambda.Start(handleRequest)
}
```

This `main.go` file contains the following sections of code:

- `package main`: In Go, the package containing your `func main()` function must always be named `main`.
- `import` block: Use this block to include libraries that your Lambda function requires.
- `type Order struct {}` block: Define the shape of the expected input event in this Go struct.
- `var ()` block: Use this block to define any global variables that you'll use in your Lambda function.
- `func init() {}`: Include any code you want Lambda to run during the [initialization phase](#) in this `init()` method.
- `func uploadReceiptToS3(...) {}`: This is a helper method that's referenced by the main `handleRequest` handler method.
- `func handleRequest(ctx context.Context, event json.RawMessage) error {}`: This is the **main handler method**, which contains your main application logic.
- `func main() {}`: This is a required entry point for your Lambda handler. The argument to the `lambda.Start()` method is your main handler method.

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

Handler naming conventions

For Lambda functions in Go, you can use any name for the handler. In this example, the handler method name is `handleRequest`. To reference the handler value in your code, you can use the `_HANDLER` environment variable.

For Go functions deployed using a [.zip deployment package](#), the executable file that contains your function code must be named `bootstrap`. In addition, the `bootstrap` file must be at the root of the `.zip` file. For Go functions deployed using a [container image](#), you can use any name for the executable file.

Defining and accessing the input event object

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "order_id": "12345",
  "amount": 199.99,
  "item": "Wireless Headphones"
}
```

When working with Lambda functions in Go, you can define the shape of the expected input event as a Go struct. In this example, we define a struct to represent an `Order`:

```
type Order struct {
  OrderID string `json:"order_id"`
  Amount  float64 `json:"amount"`
  Item    string `json:"item"`
}
```

This struct matches the expected input shape. After you define your struct, you can write a handler signature that takes in a generic JSON type compatible with the [encoding/json standard library](#). You can then deserialize it into your struct using the [func Unmarshal](#) function. This is illustrated in the first few lines of the handler:

```
func handleRequest(ctx context.Context, event json.RawMessage) error {
  // Parse the input event
  var order Order
  if err := json.Unmarshal(event, &order); err != nil {
```

```
    log.Printf("Failed to unmarshal event: %v", err)
    return err
    ...
}
```

After this deserialization, you can access the fields of the order variable. For example, `order.OrderID` retrieves the value of "order_id" from the original input.

Note

The `encoding/json` package can access only exported fields. To be exported, field names in the event struct must be capitalized.

Accessing and using the Lambda context object

The Lambda [context object](#) contains information about the invocation, function, and execution environment. In this example, we declared this variable as `ctx` in the handler signature:

```
func handleRequest(ctx context.Context, event json.RawMessage) error {
    ...
}
```

The `ctx context.Context` input is an optional argument in your function handler. For more information about accepted handler signatures, see [the section called “Valid handler signatures for Go handlers”](#).

If you make calls to other services using the AWS SDK, the context object is required in a few key areas. For example, to properly initialize your SDK clients, you can load the correct AWS SDK configuration using the context object as follows:

```
// Load AWS SDK configuration using the default credential provider chain
cfg, err := config.LoadDefaultConfig(ctx)
```

SDK calls themselves may require the context object as an input. For example, the `s3Client.PutObject` call accepts the context object as its first argument:

```
// Upload the receipt to S3
_, err = s3Client.PutObject(ctx, &s3.PutObjectInput{
    ...
}
```

```
} )
```

Outside of AWS SDK requests, you can also use the context object for function monitoring. For more information about the context object, see [the section called “Context”](#).

Valid handler signatures for Go handlers

You have several options when building a Lambda function handler in Go, but you must adhere to the following rules:

- The handler must be a function.
- The handler may take between 0 and 2 arguments. If there are two arguments, the first argument must implement `context.Context`.
- The handler may return between 0 and 2 arguments. If there is a single return value, it must implement `error`. If there are two return values, the second value must implement `error`.

The following lists valid handler signatures. `TIn` and `TOut` represent types compatible with the *encoding/json* standard library. For more information, see [func Unmarshal](#) to learn how these types are deserialized.

- `func ()`
- `func () error`
- `func () (TOut, error)`
- `func (TIn) error`
- `func (TIn) (TOut, error)`
- `func (context.Context) error`
- `func (context.Context) (TOut, error)`
- `func (context.Context, TIn) error`
- `func (context.Context, TIn) (TOut, error)`

Using the AWS SDK for Go v2 in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the [AWS SDK for Go v2](#).

Note

The AWS SDK for Go (v1) is in maintenance mode, and will reach end-of-support on July 31, 2025. We recommend that you use only the AWS SDK for Go v2 going forward.

To add SDK dependencies to your function, use the `go get` command for the specific SDK clients that you need. In the example code earlier, we used the `config` library and the `s3` library. Add these dependencies by running the following commands in the directory that contains your `go.mod` and `main.go` files:

```
go get github.com/aws/aws-sdk-go-v2/config
go get github.com/aws/aws-sdk-go-v2/service/s3
```

Then, import the dependencies accordingly in your function's import block:

```
import (
    ...
    "github.com/aws/aws-sdk-go-v2/config"
    "github.com/aws/aws-sdk-go-v2/service/s3"
)
```

When using the SDK in your handler, configure your clients with the right settings. The simplest way to do this is to use the [default credential provider chain](#). This example illustrates one way to load this configuration:

```
// Load AWS SDK configuration using the default credential provider chain
cfg, err := config.LoadDefaultConfig(ctx)
if err != nil {
    log.Printf("Failed to load AWS SDK config: %v", err)
    return err
}
```

After loading this configuration into the `cfg` variable, you can pass this variable into client instantiations. The example code instantiates an Amazon S3 client as follows:

```
// Create an S3 client
s3Client := s3.NewFromConfig(cfg)
```

In this example, we initialized our Amazon S3 client in the `init()` function to avoid having to initialize it every time we invoke our function. The problem is that in the `init()` function, Lambda doesn't have access to the context object. As a workaround, you can pass in a placeholder like `context.TODO()` during the initialization phase. Later, when you make a call using the client, pass in the full context object. This workaround is also described in [the section called “Using the context in AWS SDK client initializations and calls”](#).

After you configure and initialize your SDK client, you can then use it to interact with other AWS services. The example code calls the Amazon S3 `PutObject` API as follows:

```
_, err = s3Client.PutObject(ctx, &s3.PutObjectInput{
    Bucket: &bucketName,
    Key:    &key,
    Body:   strings.NewReader(receiptContent),
})
```

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using the `os.Getenv()` method. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following line of code:

```
// Access environment variables
bucketName := os.Getenv("RECEIPT_BUCKET")
if bucketName == "" {
    log.Printf("RECEIPT_BUCKET environment variable is not set")
    return fmt.Errorf("missing required environment variable RECEIPT_BUCKET")
}
```

Using global state

To avoid creating new resources every time you invoke your function, you can declare and modify global variables outside of your Lambda function's handler code. You define these global variables in a `var` block or statement. In addition, your handler may declare an `init()` function that is executed during the [initialization phase](#). The `init` method behaves the same in AWS Lambda as it does in standard Go programs.

Code best practices for Go Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation.

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Using the Lambda context object to retrieve Go function information

In Lambda, the context object provides methods and properties with information about the invocation, function, and execution environment. When Lambda runs your function, it passes a context object to the [handler](#). To use the context object in your handler, you can optionally declare it as an input parameter to your handler. The context object is necessary if you want to do the following in your handler:

- You need access to any of the [global variables, methods, or properties](#) offered by the context object. These methods and properties are useful for tasks like determining the entity that invoked your function or measuring the invocation time of your function, as illustrated in [the section called “Accessing invoke context information”](#).
- You need to use the AWS SDK for Go to make calls to other services. The context object is an important input parameter to most of these calls. For more information, see [the section called “Using the context in AWS SDK client initializations and calls”](#).

Topics

- [Supported variables, methods, and properties in the context object](#)
- [Accessing invoke context information](#)
- [Using the context in AWS SDK client initializations and calls](#)

Supported variables, methods, and properties in the context object

The Lambda context library provides the following global variables, methods, and properties.

Global variables

- `FunctionName` – The name of the Lambda function.
- `FunctionVersion` – The [version](#) of the function.
- `MemoryLimitInMB` – The amount of memory that's allocated for the function.
- `LogGroupName` – The log group for the function.
- `LogStreamName` – The log stream for the function instance.

Context methods

- **Deadline** – Returns the date that the execution times out, in Unix time milliseconds.

Context properties

- **InvokedFunctionArn** – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- **AwsRequestID** – The identifier of the invocation request.
- **Identity** – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
- **ClientContext** – (mobile apps) Client context that's provided to Lambda by the client application.

Accessing invoke context information

Lambda functions have access to metadata about their environment and the invocation request. This can be accessed at [Package context](#). Should your handler include `context.Context` as a parameter, Lambda will insert information about your function into the context's `Value` property. Note that you need to import the `lambdacontext` library to access the contents of the `context.Context` object.

```
package main

import (
    "context"
    "log"
    "github.com/aws/aws-lambda-go/lambda"
    "github.com/aws/aws-lambda-go/lambdacontext"
)

func CognitoHandler(ctx context.Context) {
    lc, _ := lambdacontext.FromContext(ctx)
    log.Print(lc.Identity.CognitoIdentityPoolID)
}

func main() {
    lambda.Start(CognitoHandler)
```

```
}
```

In the example above, `lc` is the variable used to consume the information that the context object captured and `log.Print(lc.Identity.CognitoIdentityPoolID)` prints that information, in this case, the `CognitoIdentityPoolID`.

The following example introduces how to use the context object to monitor how long your Lambda function takes to complete. This allows you to analyze performance expectations and adjust your function code accordingly, if needed.

```
package main

import (
    "context"
    "log"
    "time"
    "github.com/aws/aws-lambda-go/lambda"
)

func LongRunningHandler(ctx context.Context) (string, error) {

    deadline, _ := ctx.Deadline()
    deadline = deadline.Add(-100 * time.Millisecond)
    timeoutChannel := time.After(time.Until(deadline))

    for {

        select {

            case <- timeoutChannel:
                return "Finished before timing out.", nil

            default:
                log.Print("hello!")
                time.Sleep(50 * time.Millisecond)
        }
    }
}

func main() {
    lambda.Start(LongRunningHandler)
}
```

Using the context in AWS SDK client initializations and calls

If your handler needs to use the AWS SDK for Go to make calls to other services, include the context object as an input to your handler. In AWS, it's a best practice to pass in the context object in most AWS SDK calls. For example, the Amazon S3 `PutObject` call accepts the context object (`ctx`) as its first argument:

```
// Upload an object to S3
_, err = s3Client.PutObject(ctx, &s3.PutObjectInput{
    ...
})
```

To initialize your SDK clients properly, you can also use the context object to load the correct configuration before passing that configuration object to the client:

```
// Load AWS SDK configuration using the default credential provider chain
cfg, err := config.LoadDefaultConfig(ctx)
...
s3Client = s3.NewFromConfig(cfg)
```

If you want to initialize your SDK clients outside of your main handler (i.e. during the initialization phase), you can pass in a placeholder context object:

```
func init() {
    // Initialize the S3 client outside of the handler, during the init phase
    cfg, err := config.LoadDefaultConfig(context.TODO())
    ...
    s3Client = s3.NewFromConfig(cfg)
}
```

If you initialize your clients this way, ensure that you pass in the correct context object in SDK calls from your main handler.

Deploy Go Lambda functions with .zip file archives

Your AWS Lambda function's code consists of scripts or compiled programs and their dependencies. You use a *deployment package* to deploy your function code to Lambda. Lambda supports two types of deployment packages: container images and .zip file archives.

This page describes how to create a .zip file as your deployment package for the Go runtime, and then use the .zip file to deploy your function code to AWS Lambda using the AWS Management Console, AWS Command Line Interface (AWS CLI), and AWS Serverless Application Model (AWS SAM).

Note that Lambda uses POSIX file permissions, so you may need to [set permissions for the deployment package folder](#) before you create the .zip file archive.

Sections

- [Creating a .zip file on macOS and Linux](#)
- [Creating a .zip file on Windows](#)
- [Creating and updating Go Lambda functions using .zip files](#)

Creating a .zip file on macOS and Linux

The following steps show how to compile your executable using the `go build` command and create a .zip file deployment package for Lambda. Before compiling your code, make sure you have installed the [lambda](#) package from GitHub. This module provides an implementation of the runtime interface, which manages the interaction between Lambda and your function code. To download this library, run the following command.

```
go get github.com/aws/aws-lambda-go/lambda
```

If your function uses the AWS SDK for Go, download the standard set of SDK modules, along with any AWS service API clients required by your application. To learn how to install the SDK for Go, see [Getting Started with the AWS SDK for Go V2](#).

Using the provided runtime family

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only runtime](#) (the provided runtime family) to deploy Go functions to Lambda.

To create a .zip deployment package (macOS/Linux)

1. In the project directory that contains your application's `main.go` file, compile your executable. Note the following:

- The executable must be named `bootstrap`. For more information, see [Handler naming conventions](#).
- Set your target [instruction set architecture](#). OS-only runtimes support both `arm64` and `x86_64`.
- You can use the optional `lambda.norpc` tag to exclude the Remote Procedure Call (RPC) component of the [lambda](#) library. The RPC component is only required if you are using the deprecated Go 1.x runtime. Excluding the RPC reduces the size of the deployment package.

For the `arm64` architecture:

```
GOOS=linux GOARCH=arm64 go build -tags lambda.norpc -o bootstrap main.go
```

For the `x86_64` architecture:

```
GOOS=linux GOARCH=amd64 go build -tags lambda.norpc -o bootstrap main.go
```

2. (Optional) You may need to compile packages with `CGO_ENABLED=0` set on Linux:

```
GOOS=linux GOARCH=arm64 CGO_ENABLED=0 go build -o bootstrap -tags lambda.norpc main.go
```

This command creates a stable binary package for standard C library (`libc`) versions, which may be different on Lambda and other devices.

3. Create a deployment package by packaging the executable in a .zip file.

```
zip myFunction.zip bootstrap
```

Note

The `bootstrap` file must be at the root of the .zip file.

4. Create the function. Note the following:

- The binary must be named `bootstrap`, but the handler name can be anything. For more information, see [Handler naming conventions](#).
- The `--architectures` option is only required if you're using `arm64`. The default value is `x86_64`.
- For `--role`, specify the Amazon Resource Name (ARN) of the [execution role](#).

```
aws lambda create-function --function-name myFunction \  
--runtime provided.al2023 --handler bootstrap \  
--architectures arm64 \  
--role arn:aws:iam::111122223333:role/lambda-ex \  
--zip-file fileb://myFunction.zip
```

Creating a .zip file on Windows

The following steps show how to download the [build-lambda-zip](#) tool for Windows from GitHub, compile your executable, and create a .zip deployment package.

Note

If you have not already done so, you must install [git](#) and then add the `git` executable to your Windows `%PATH%` environment variable.

Before compiling your code, make sure you have installed the [lambda](#) library from GitHub. To download this library, run the following command.

```
go get github.com/aws/aws-lambda-go/lambda
```

If your function uses the AWS SDK for Go, download the standard set of SDK modules, along with any AWS service API clients required by your application. To learn how to install the SDK for Go, see [Getting Started with the AWS SDK for Go V2](#).

Using the provided runtime family

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only runtime](#) (the provided runtime family) to deploy Go functions to Lambda.

To create a .zip deployment package (Windows)

1. Download the **build-lambda-zip** tool from GitHub.

```
go install github.com/aws/aws-lambda-go/cmd/build-lambda-zip@latest
```

2. Use the tool from your GOPATH to create a .zip file. If you have a default installation of Go, the tool is typically in %USERPROFILE%\Go\bin. Otherwise, navigate to where you installed the Go runtime and do one of the following:

cmd.exe

In cmd.exe, run one of the following, depending on your target [instruction set architecture](#). OS-only runtimes support both arm64 and x86_64.

You can use the optional `lambda.norpc` tag to exclude the Remote Procedure Call (RPC) component of the [lambda](#) library. The RPC component is only required if you are using the deprecated Go 1.x runtime. Excluding the RPC reduces the size of the deployment package.

Example — For the x86_64 architecture

```
set GOOS=linux
set GOARCH=amd64
set CGO_ENABLED=0
go build -tags lambda.norpc -o bootstrap main.go
%USERPROFILE%\Go\bin\build-lambda-zip.exe -o myFunction.zip bootstrap
```

Example — For the arm64 architecture

```
set GOOS=linux
set GOARCH=arm64
set CGO_ENABLED=0
go build -tags lambda.norpc -o bootstrap main.go
%USERPROFILE%\Go\bin\build-lambda-zip.exe -o myFunction.zip bootstrap
```

PowerShell

In PowerShell, run one of the following, depending on your target [instruction set architecture](#). OS-only runtimes support both arm64 and x86_64.

You can use the optional `lambda.norpc` tag to exclude the Remote Procedure Call (RPC) component of the [lambda](#) library. The RPC component is only required if you are using the deprecated Go 1.x runtime. Excluding the RPC reduces the size of the deployment package.

For the x86_64 architecture:

```
$env:GOOS = "linux"
$env:GOARCH = "amd64"
$env:CGO_ENABLED = "0"
go build -tags lambda.norpc -o bootstrap main.go
~\Go\Bin\build-lambda-zip.exe -o myFunction.zip bootstrap
```

For the arm64 architecture:

```
$env:GOOS = "linux"
$env:GOARCH = "arm64"
$env:CGO_ENABLED = "0"
go build -tags lambda.norpc -o bootstrap main.go
~\Go\Bin\build-lambda-zip.exe -o myFunction.zip bootstrap
```

3. Create the function. Note the following:

- The binary must be named `bootstrap`, but the handler name can be anything. For more information, see [Handler naming conventions](#).
- The `--architectures` option is only required if you're using arm64. The default value is `x86_64`.
- For `--role`, specify the Amazon Resource Name (ARN) of the [execution role](#).

```
aws lambda create-function --function-name myFunction \
--runtime provided.al2023 --handler bootstrap \
--architectures arm64 \
--role arn:aws:iam::111122223333:role/lambda-ex \
--zip-file fileb://myFunction.zip
```

Creating and updating Go Lambda functions using .zip files

After you have created your .zip deployment package, you can use it to create a new Lambda function or update an existing one. You can deploy your .zip package using the Lambda console, the AWS Command Line Interface, and the Lambda API. You can also create and update Lambda functions using AWS Serverless Application Model (AWS SAM) and CloudFormation.

The maximum size for a .zip deployment package for Lambda is 250 MB (unzipped). Note that this limit applies to the combined size of all the files you upload, including any Lambda layers.

The Lambda runtime needs permission to read the files in your deployment package. In Linux permissions octal notation, Lambda needs 644 permissions for non-executable files (rw-r--r--) and 755 permissions (rwxr-xr-x) for directories and executable files.

In Linux and MacOS, use the `chmod` command to change file permissions on files and directories in your deployment package. For example, to give a non-executable file the correct permissions, run the following command.

```
chmod 644 <filepath>
```

To change file permissions in Windows, see [Set, View, Change, or Remove Permissions on an Object](#) in the Microsoft Windows documentation.

Note

If you don't grant Lambda the permissions it needs to access directories in your deployment package, Lambda sets the permissions for those directories to 755 (rwxr-xr-x).

Creating and updating functions with .zip files using the console

To create a new function, you must first create the function in the console, then upload your .zip archive. To update an existing function, open the page for your function, then follow the same procedure to add your updated .zip file.

If your .zip file is less than 50MB, you can create or update a function by uploading the file directly from your local machine. For .zip files greater than 50MB, you must upload your package to an Amazon S3 bucket first. For instructions on how to upload a file to an Amazon S3 bucket using the

AWS Management Console, see [Getting started with Amazon S3](#). To upload files using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

 **Note**

You cannot convert an existing container image function to use a .zip archive. You must create a new function.

To create a new function (console)

1. Open the [Functions page](#) of the Lambda console and choose **Create Function**.
2. Choose **Author from scratch**.
3. Under **Basic information**, do the following:
 - a. For **Function name**, enter the name for your function.
 - b. For **Runtime**, choose `provided.al2023`.
4. (Optional) Under **Permissions**, expand **Change default execution role**. You can create a new **Execution role** or use an existing one.
5. Choose **Create function**. Lambda creates a basic 'Hello world' function using your chosen runtime.

To upload a .zip archive from your local machine (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload the .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **.zip file**.
5. To upload the .zip file, do the following:
 - a. Select **Upload**, then select your .zip file in the file chooser.
 - b. Choose **Open**.
 - c. Choose **Save**.

To upload a .zip archive from an Amazon S3 bucket (console)

1. In the [Functions page](#) of the Lambda console, choose the function you want to upload a new .zip file for.
2. Select the **Code** tab.
3. In the **Code source** pane, choose **Upload from**.
4. Choose **Amazon S3 location**.
5. Paste the Amazon S3 link URL of your .zip file and choose **Save**.

Creating and updating functions with .zip files using the AWS CLI

You can use the [AWS CLI](#) to create a new function or to update an existing one using a .zip file. Use the [create-function](#) and [update-function-code](#) commands to deploy your .zip package. If your .zip file is smaller than 50MB, you can upload the .zip package from a file location on your local build machine. For larger files, you must upload your .zip package from an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

Note

If you upload your .zip file from an Amazon S3 bucket using the AWS CLI, the bucket must be located in the same AWS Region as your function.

To create a new function using a .zip file with the AWS CLI, you must specify the following:

- The name of your function (`--function-name`)
- Your function's runtime (`--runtime`)
- The Amazon Resource Name (ARN) of your function's [execution role](#) (`--role`)
- The name of the handler method in your function code (`--handler`)

You must also specify the location of your .zip file. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda create-function --function-name myFunction \
```

```
--runtime provided.al2023 --handler bootstrap \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--code` option as shown in the following example command. You only need to use the `S3ObjectVersion` parameter for versioned objects.

```
aws lambda create-function --function-name myFunction \  
--runtime provided.al2023 --handler bootstrap \  
--role arn:aws:iam::111122223333:role/service-role/my-lambda-role \  
--code S3Bucket=amzn-s3-demo-  
bucket,S3Key=myFileName.zip,S3ObjectVersion=myObjectVersion
```

To update an existing function using the CLI, you specify the the name of your function using the `--function-name` parameter. You must also specify the location of the .zip file you want to use to update your function code. If your .zip file is located in a folder on your local build machine, use the `--zip-file` option to specify the file path, as shown in the following example command.

```
aws lambda update-function-code --function-name myFunction \  
--zip-file fileb://myFunction.zip
```

To specify the location of .zip file in an Amazon S3 bucket, use the `--s3-bucket` and `--s3-key` options as shown in the following example command. You only need to use the `--s3-object-version` parameter for versioned objects.

```
aws lambda update-function-code --function-name myFunction \  
--s3-bucket amzn-s3-demo-bucket --s3-key myFileName.zip --s3-object-version myObject  
Version
```

Creating and updating functions with .zip files using the Lambda API

To create and update functions using a .zip file archive, use the following API operations:

- [CreateFunction](#)
- [UpdateFunctionCode](#)

Creating and updating functions with .zip files using AWS SAM

The AWS Serverless Application Model (AWS SAM) is a toolkit that helps streamline the process of building and running serverless applications on AWS. You define the resources for your application in a YAML or JSON template and use the AWS SAM command line interface (AWS SAM CLI) to build, package, and deploy your applications. When you build a Lambda function from an AWS SAM template, AWS SAM automatically creates a .zip deployment package or container image with your function code and any dependencies you specify. To learn more about using AWS SAM to build and deploy Lambda functions, see [Getting started with AWS SAM](#) in the *AWS Serverless Application Model Developer Guide*.

You can also use AWS SAM to create a Lambda function using an existing .zip file archive. To create a Lambda function using AWS SAM, you can save your .zip file in an Amazon S3 bucket or in a local folder on your build machine. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your AWS SAM template, the `AWS::Serverless::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - set to `Zip`
- `CodeUri` - set to the function code's Amazon S3 URI, path to local folder, or [FunctionCode](#) object
- `Runtime` - Set to your chosen runtime

With AWS SAM, if your .zip file is larger than 50MB, you don't need to upload it to an Amazon S3 bucket first. AWS SAM can upload .zip packages up to the maximum allowed size of 250MB (unzipped) from a location on your local build machine.

To learn more about deploying functions using .zip file in AWS SAM, see [AWS::Serverless::Function](#) in the *AWS SAM Developer Guide*.

Example: Using AWS SAM to build a Go function with `provided.al2023`

1. Create an AWS SAM template with the following properties:
 - **BuildMethod**: Specifies the compiler for your application. Use `go1.x`.
 - **Runtime**: Use `provided.al2023`.
 - **CodeUri**: Enter the path to your code.

- **Architectures:** Use `[arm64]` for the arm64 architecture. For the x86_64 instruction set architecture, use `[amd64]` or remove the `Architectures` property.

Example template.yaml

```
AWSTemplateFormatVersion: '2010-09-09'
Transform: 'AWS::Serverless-2016-10-31'
Resources:
  HelloWorldFunction:
    Type: AWS::Serverless::Function
    Metadata:
      BuildMethod: go1.x
    Properties:
      CodeUri: hello-world/ # folder where your main program resides
      Handler: bootstrap
      Runtime: provided.al2023
      Architectures: [arm64]
```

2. Use the [sam build](#) command to compile the executable.

```
sam build
```

3. Use the [sam deploy](#) command to deploy the function to Lambda.

```
sam deploy --guided
```

Creating and updating functions with .zip files using CloudFormation

You can use CloudFormation to create a Lambda function using a .zip file archive. To create a Lambda function from a .zip file, you must first upload your file to an Amazon S3 bucket. For instructions on how to upload a file to an Amazon S3 bucket using the AWS CLI, see [Move objects](#) in the *AWS CLI User Guide*.

In your CloudFormation template, the `AWS::Lambda::Function` resource specifies your Lambda function. In this resource, set the following properties to create a function using a .zip file archive:

- `PackageType` - Set to `Zip`
- `Code` - Enter the Amazon S3 bucket name and the .zip file name in the `S3Bucket` and `S3Key` fields

- Runtime - Set to your chosen runtime

The .zip file that CloudFormation generates cannot exceed 4MB. To learn more about deploying functions using .zip file in CloudFormation, see [AWS::Lambda::Function](#) in the *CloudFormation User Guide*.

Deploy Go Lambda functions with container images

There are two ways to build a container image for a Go Lambda function:

- [Using an AWS OS-only base image](#)

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only base image](#) to build Go images for Lambda. To make the image compatible with Lambda, you must include the `aws-lambda-go/lambda` package in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the `aws-lambda-go/lambda` package in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

AWS base images for deploying Go functions

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only base image](#) to deploy Go functions to Lambda.

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
OS-only Runtime	provided.al2023	Amazon Linux 2023	Jun 30, 2029	Jul 31, 2029	Aug 31, 2029

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
OS-only Runtime	provided.al2	Amazon Linux 2	Jul 31, 2026	Aug 31, 2026	Sep 30, 2026

Amazon Elastic Container Registry Public Gallery: gallery.ecr.aws/lambda/provided

Go runtime interface client

The `aws-lambda-go/lambda` package includes an implementation of the runtime interface. For examples of how to use `aws-lambda-go/lambda` in your image, see [Using an AWS OS-only base image](#) or [Using a non-AWS base image](#).

Using an AWS OS-only base image

Go is implemented differently than other managed runtimes. Because Go compiles natively to an executable binary, it doesn't require a dedicated language runtime. Use an [OS-only base image](#) to build container images for Go functions.

Tags	Runtime	Operating system	Dockerfile	Deprecation
al2023	OS-only Runtime	Amazon Linux 2023	Dockerfile for OS-only Runtime on GitHub	Jun 30, 2029
al2	OS-only Runtime	Amazon Linux 2	Dockerfile for OS-only Runtime on GitHub	Jul 31, 2026

For more information about these base images, see [provided](#) in the Amazon ECR public gallery.

You must include the [aws-lambda-go/lambda](#) package with your Go handler. This package implements the programming model for Go, including the runtime interface.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Go

Creating an image from the provided.al2023 base image

To build and deploy a Go function with the provided.al2023 base image

1. Create a directory for the project, and then switch to that directory.

```
mkdir hello
cd hello
```

2. Initialize a new Go module.

```
go mod init example.com/hello-world
```

3. Add the **lambda** library as a dependency of your new module.

```
go get github.com/aws/aws-lambda-go/lambda
```

4. Create a file named `main.go` and then open it in a text editor. This is the code for the Lambda function. You can use the following sample code for testing, or replace it with your own.

```
package main

import (
    "context"
    "github.com/aws/aws-lambda-go/events"
    "github.com/aws/aws-lambda-go/lambda"
)

func handler(ctx context.Context, event events.APIGatewayProxyRequest)
(event events.APIGatewayProxyResponse, error) {
    response := events.APIGatewayProxyResponse{
        StatusCode: 200,
        Body:       "\"Hello from Lambda!\"",
    }
    return response, nil
}
```

```
}

func main() {
    lambda.Start(handler)
}
```

5. Use a text editor to create a Dockerfile in your project directory.

- The following example Dockerfile uses a [multi-stage build](#). This allows you to use a different base image in each step. You can use one image, such as a [Go base image](#), to compile your code and build the executable binary. You can then use a different image, such as `provided.al2023`, in the final FROM statement to define the image that you deploy to Lambda. The build process is separated from the final deployment image, so the final image only contains the files needed to run the application.
- You can use the optional `lambda.norpc` tag to exclude the Remote Procedure Call (RPC) component of the [lambda](#) library. The RPC component is only required if you are using the deprecated Go 1.x runtime. Excluding the RPC reduces the size of the deployment package.
- Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example— Multi-stage build Dockerfile

Note

Make sure that the version of Go that you specify in your Dockerfile (for example, `golang:1.20`) is the same version of Go that you used to create your application.

```
FROM golang:1.20 as build
WORKDIR /helloworld
# Copy dependencies list
COPY go.mod go.sum ./
# Build with optional lambda.norpc tag
COPY main.go .
RUN go build -tags lambda.norpc -o main main.go
# Copy artifacts to a clean image
FROM public.ecr.aws/lambda/provided:al2023
```

```
COPY --from=build /helloworld/main ./main
ENTRYPOINT [ "./main" ]
```

6. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test your image. The runtime interface emulator is included in the provided `.al2023` base image.

To run the runtime interface emulator on your local machine

1. Start the Docker image with the **docker run** command. Note the following:
 - `docker-image` is the image name and `test` is the tag.
 - `./main` is the ENTRYPOINT from your Dockerfile.

```
docker run -d -p 9000:8080 \
--entrypoint /usr/local/bin/aws-lambda-rie \
docker-image:test ./main
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

2. From a new terminal window, post an event to the following endpoint using a **curl** command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. Some functions might require a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d  
'{"payload":"hello world!"}'
```

3. Get the container ID.

```
docker ps
```

4. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.
 - Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
 - Replace 111122223333 with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --  
password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-  
scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.
4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Using a non-AWS base image

You can build a container image for Go from a non-AWS base image. The example Dockerfile in the following steps uses an [Alpine base image](#).

You must include the [aws-lambda-go/lambda](#) package with your Go handler. This package implements the programming model for Go, including the runtime interface.

Prerequisites

To complete the steps in this section, you must have the following:

- [AWS CLI version 2](#)
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).
- Go

Creating an image from an alternative base image

To build and deploy a Go function with an Alpine base image

1. Create a directory for the project, and then switch to that directory.

```
mkdir hello
cd hello
```

2. Initialize a new Go module.

```
go mod init example.com/hello-world
```

3. Add the **lambda** library as a dependency of your new module.

```
go get github.com/aws/aws-lambda-go/lambda
```

4. Create a file named `main.go` and then open it in a text editor. This is the code for the Lambda function. You can use the following sample code for testing, or replace it with your own.

```
package main

import (
    "context"
    "github.com/aws/aws-lambda-go/events"
    "github.com/aws/aws-lambda-go/lambda"
)

func handler(ctx context.Context, event events.APIGatewayProxyRequest)
(event events.APIGatewayProxyResponse, error) {
    response := events.APIGatewayProxyResponse{
        StatusCode: 200,
        Body:       "\"Hello from Lambda!\"",
    }
    return response, nil
}

func main() {
    lambda.Start(handler)
}
```

5. Use a text editor to create a Dockerfile in your project directory. The following example Dockerfile uses an [Alpine base image](#). Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

Note

Make sure that the version of Go that you specify in your Dockerfile (for example, `golang:1.20`) is the same version of Go that you used to create your application.

```
FROM golang:1.20.2-alpine3.16 as build
WORKDIR /helloworld
# Copy dependencies list
COPY go.mod go.sum ./
# Build
COPY main.go .
RUN go build -o main main.go
# Copy artifacts to a clean image
FROM alpine:3.16
COPY --from=build /helloworld/main /main
ENTRYPOINT [ "/main" ]
```

6. Build the Docker image with the [docker build](#) command. The following example names the image `docker-image` and gives it the test [tag](#). To make your image compatible with Lambda, you must use the `--provenance=false` option.

```
docker buildx build --platform linux/amd64 --provenance=false -t docker-image:test .
```

Note

The command specifies the `--platform linux/amd64` option to ensure that your container is compatible with the Lambda execution environment regardless of the architecture of your build machine. If you intend to create a Lambda function using the ARM64 instruction set architecture, be sure to change the command to use the `--platform linux/arm64` option instead.

(Optional) Test the image locally

Use the [runtime interface emulator](#) to locally test the image. You can [build the emulator into your image](#) or use the following procedure to install it on your local machine.

To install and run the runtime interface emulator on your local machine

1. From your project directory, run the following command to download the runtime interface emulator (x86-64 architecture) from GitHub and install it on your local machine.

Linux/macOS

```
mkdir -p ~/.aws-lambda-rie && \  
  curl -Lo ~/.aws-lambda-rie/aws-lambda-rie https://github.com/aws/aws-lambda-  
runtime-interface-emulator/releases/latest/download/aws-lambda-rie && \  
  chmod +x ~/.aws-lambda-rie/aws-lambda-rie
```

To install the arm64 emulator, replace the GitHub repository URL in the previous command with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/  
download/aws-lambda-rie-arm64
```

PowerShell

```
$dirPath = "$HOME\.aws-lambda-rie"  
if (-not (Test-Path $dirPath)) {  
    New-Item -Path $dirPath -ItemType Directory  
}  
  
$downloadLink = "https://github.com/aws/aws-lambda-runtime-interface-emulator/  
releases/latest/download/aws-lambda-rie"  
$destinationPath = "$HOME\.aws-lambda-rie\aws-lambda-rie"  
Invoke-WebRequest -Uri $downloadLink -OutFile $destinationPath
```

To install the arm64 emulator, replace the `$downloadLink` with the following:

```
https://github.com/aws/aws-lambda-runtime-interface-emulator/releases/latest/  
download/aws-lambda-rie-arm64
```

2. Start the Docker image with the **docker run** command. Note the following:

- `docker-image` is the image name and `test` is the tag.
- `/main` is the ENTRYPOINT from your Dockerfile.

Linux/macOS

```
docker run --platform linux/amd64 -d -v ~/.aws-lambda-rie:/aws-lambda -p
9000:8080 \
  --entrypoint /aws-lambda/aws-lambda-rie \
  docker-image:test \
  /main
```

PowerShell

```
docker run --platform linux/amd64 -d -v "$HOME\.aws-lambda-rie:/aws-lambda" -p
9000:8080 `
--entrypoint /aws-lambda/aws-lambda-rie `
docker-image:test `
/main
```

This command runs the image as a container and creates a local endpoint at `localhost:9000/2015-03-31/functions/function/invocations`.

Note

If you built the Docker image for the ARM64 instruction set architecture, be sure to use the `--platform linux/arm64` option instead of `--platform linux/amd64`.

3. Post an event to the local endpoint.

Linux/macOS

In Linux and macOS, run the following `curl` command:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d '{}'
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
curl "http://localhost:9000/2015-03-31/functions/function/invocations" -d
'{"payload":"hello world!"}'
```

PowerShell

In PowerShell, run the following Invoke-WebRequest command:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/
invocations" -Method Post -Body '{}' -ContentType "application/json"
```

This command invokes the function with an empty event and returns a response. If you're using your own function code rather than the sample function code, you might want to invoke the function with a JSON payload. Example:

```
Invoke-WebRequest -Uri "http://localhost:9000/2015-03-31/functions/function/
invocations" -Method Post -Body '{"payload":"hello world!"}' -ContentType
"application/json"
```

4. Get the container ID.

```
docker ps
```

5. Use the [docker kill](#) command to stop the container. In this command, replace 3766c4ab331c with the container ID from the previous step.

```
docker kill 3766c4ab331c
```

Deploying the image

To upload the image to Amazon ECR and create the Lambda function

1. Run the [get-login-password](#) command to authenticate the Docker CLI to your Amazon ECR registry.

- Set the `--region` value to the AWS Region where you want to create the Amazon ECR repository.
- Replace `111122223333` with your AWS account ID.

```
aws ecr get-login-password --region us-east-1 | docker login --username AWS --password-stdin 111122223333.dkr.ecr.us-east-1.amazonaws.com
```

2. Create a repository in Amazon ECR using the [create-repository](#) command.

```
aws ecr create-repository --repository-name hello-world --region us-east-1 --image-scanning-configuration scanOnPush=true --image-tag-mutability MUTABLE
```

Note

The Amazon ECR repository must be in the same AWS Region as the Lambda function.

If successful, you see a response like this:

```
{
  "repository": {
    "repositoryArn": "arn:aws:ecr:us-east-1:111122223333:repository/hello-world",
    "registryId": "111122223333",
    "repositoryName": "hello-world",
    "repositoryUri": "111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world",
    "createdAt": "2023-03-09T10:39:01+00:00",
    "imageTagMutability": "MUTABLE",
    "imageScanningConfiguration": {
      "scanOnPush": true
    },
    "encryptionConfiguration": {
      "encryptionType": "AES256"
    }
  }
}
```

3. Copy the `repositoryUri` from the output in the previous step.

4. Run the [docker tag](#) command to tag your local image into your Amazon ECR repository as the latest version. In this command:
 - `docker-image:test` is the name and [tag](#) of your Docker image. This is the image name and tag that you specified in the `docker build` command.
 - Replace `<ECRrepositoryUri>` with the `repositoryUri` that you copied. Make sure to include `:latest` at the end of the URI.

```
docker tag docker-image:test <ECRrepositoryUri>:latest
```

Example:

```
docker tag docker-image:test 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

5. Run the [docker push](#) command to deploy your local image to the Amazon ECR repository. Make sure to include `:latest` at the end of the repository URI.

```
docker push 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest
```

6. [Create an execution role](#) for the function, if you don't already have one. You need the Amazon Resource Name (ARN) of the role in the next step.
7. Create the Lambda function. For `ImageUri`, specify the repository URI from earlier. Make sure to include `:latest` at the end of the URI.

```
aws lambda create-function \
  --function-name hello-world \
  --package-type Image \
  --code ImageUri=111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \
  --role arn:aws:iam::111122223333:role/lambda-ex
```

Note

You can create a function using an image in a different AWS account, as long as the image is in the same Region as the Lambda function. For more information, see [Amazon ECR cross-account permissions](#).

8. Invoke the function.

```
aws lambda invoke --function-name hello-world response.json
```

You should see a response like this:

```
{
  "ExecutedVersion": "$LATEST",
  "StatusCode": 200
}
```

9. To see the output of the function, check the `response.json` file.

To update the function code, you must build the image again, upload the new image to the Amazon ECR repository, and then use the [update-function-code](#) command to deploy the image to the Lambda function.

Lambda resolves the image tag to a specific image digest. This means that if you point the image tag that was used to deploy the function to a new image in Amazon ECR, Lambda doesn't automatically update the function to use the new image.

To deploy the new image to the same Lambda function, you must use the [update-function-code](#) command, even if the image tag in Amazon ECR remains the same. In the following example, the `--publish` option creates a new version of the function using the updated container image.

```
aws lambda update-function-code \  
  --function-name hello-world \  
  --image-uri 111122223333.dkr.ecr.us-east-1.amazonaws.com/hello-world:latest \  
  --publish
```

Working with layers for Go Lambda functions

We don't recommend using [layers](#) to manage dependencies for Lambda functions written in Go. This is because Lambda functions in Go compile into a single executable, which you provide to Lambda when you deploy your function. This executable contains your compiled function code, along with all of its dependencies. Using layers not only complicates this process, but also leads to increased cold start times because your functions need to manually load extra assemblies into memory during the init phase.

To use external dependencies with your Go handlers, include them directly in your deployment package. By doing so, you simplify the deployment process and also take advantage of built-in Go compiler optimizations. For an example of how to import and use a dependency like the AWS SDK for Go in your function, see [the section called "Handler"](#).

Log and monitor Go Lambda functions

AWS Lambda automatically monitors Lambda functions on your behalf and sends logs to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation to the log stream, and relays logs and other output from your function's code. For more information, see [Sending Lambda function logs to CloudWatch Logs](#).

This page describes how to produce log output from your Lambda function's code, and access logs using the AWS Command Line Interface, the Lambda console, or the CloudWatch console.

Sections

- [Creating a function that returns logs](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)
- [Viewing logs using the AWS Command Line Interface \(AWS CLI\)](#)
- [Deleting logs](#)

Creating a function that returns logs

To output logs from your function code, you can use methods on [the `fmt` package](#), or any logging library that writes to `stdout` or `stderr`. The following example uses [the `log` package](#).

Example [main.go](#) – Logging

```
func handleRequest(ctx context.Context, event events.SQSEvent) (string, error) {
    // event
    eventJson, _ := json.MarshalIndent(event, "", " ")
    log.Printf("EVENT: %s", eventJson)
    // environment variables
    log.Printf("REGION: %s", os.Getenv("AWS_REGION"))
    log.Println("ALL ENV VARS:")
    for _, element := range os.Environ() {
        log.Println(element)
    }
}
```

Example log format

```
START RequestId: dbda340c-xmpl-4031-8810-11bb609b4c71 Version: $LATEST
```

```

2020/03/27 03:40:05 AWS_LAMBDA_FUNCTION_VERSION=$LATEST
2020/03/27 03:40:05 AWS_EXECUTION_ENV=AWS_Lambda_go1.x
END RequestId: dbda340c-xmpl-4031-8810-11bb609b4c71
REPORT RequestId: dbda340c-xmpl-4031-8810-11bb609b4c71 Duration: 38.66 ms Billed
Duration: 243 ms Memory Size: 128 MB Max Memory Used: 54 MB Init Duration: 203.69 ms
XRAY TraceId: 1-5e7d7595-212fxmpl9ee07c4884191322 SegmentId: 42ffxmpl0645f474 Sampled:
true

```

The Go runtime logs the START, END, and REPORT lines for each invocation. The report line provides the following details.

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.

- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBUlQgUmVxdWVzdElk0iA4N2QwNDRI0C1mMTU0LTExZTgt0GNkYS0yOTc0YzVlNGZiMjEgVmVyc2lvb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ22luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB
```

The `base64` utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"/'/g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
```

```

}
{
  "events": [

}

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Instrumenting Go code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of two SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for Go](#) – An SDK for generating and sending trace data to X-Ray.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

Sections

- [Using ADOT to instrument your Go functions](#)
- [Using the X-Ray SDK to instrument your Go functions](#)
- [Activating tracing with the Lambda console](#)
- [Activating tracing with the Lambda API](#)
- [Activating tracing with CloudFormation](#)
- [Interpreting an X-Ray trace](#)

Using ADOT to instrument your Go functions

ADOT provides fully managed Lambda [layers](#) that package everything you need to collect telemetry data using the OTel SDK. By consuming this layer, you can instrument your Lambda functions without having to modify any function code. You can also configure your layer to do custom initialization of OTel. For more information, see [Custom configuration for the ADOT Collector on Lambda](#) in the ADOT documentation.

For Go runtimes, you can add the **AWS managed Lambda layer for ADOT Go** to automatically instrument your functions. For detailed instructions on how to add this layer, see [AWS Distro for OpenTelemetry Lambda Support for Go](#) in the ADOT documentation.

Using the X-Ray SDK to instrument your Go functions

To record details about calls that your Lambda function makes to other resources in your application, you can also use the AWS X-Ray SDK for Go. To get the SDK, download the SDK from its [GitHub repository](#) with `go get`:

```
go get github.com/aws/aws-xray-sdk-go
```

To instrument AWS SDK clients, pass the client to the `xray.AWS()` method. You can then trace calls by using the `WithContext` version of the method.

```
svc := s3.New(session.New())
xray.AWS(svc.Client)
...
svc.ListBucketsWithContext(ctx aws.Context, input *ListBucketsInput)
```

After you add the correct dependencies and make the necessary code changes, activate tracing in your function's configuration via the Lambda console or the API.

Activating tracing with the Lambda console

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.

3. Choose **Configuration** and then choose **Monitoring and operations tools**.
4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.
6. Choose **Save**.

Activating tracing with the Lambda API

Configure tracing on your Lambda function with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Activating tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in a CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Lambda::Function
    Properties:
      TracingConfig:
        Mode: Active
```

...

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

Example [template.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Serverless::Function
    Properties:
      Tracing: Active
      ...
```

Interpreting an X-Ray trace

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

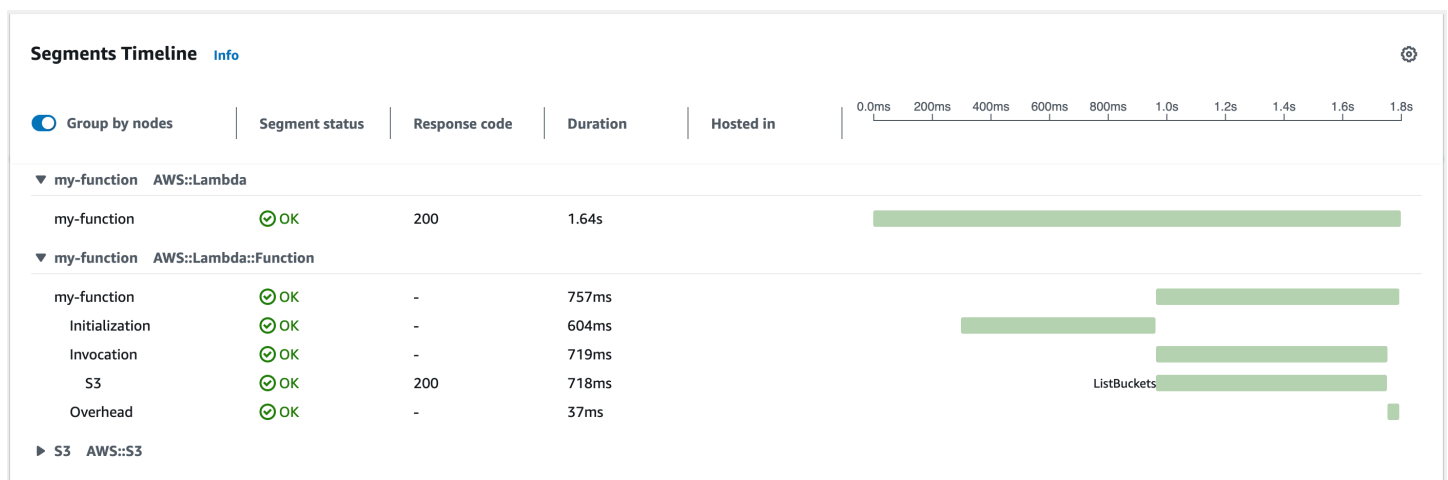

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

Note

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an Invocation subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called “Understanding X-Ray traces”](#).

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see the [AWS X-Ray SDK for Go](#) in the *AWS X-Ray Developer Guide*.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

Building Lambda functions with C#

You can run your .NET application in Lambda using the managed .NET 8 runtime, a custom runtime, or a container image. After your application code is compiled, you can deploy it to Lambda either as a .zip file or a container image. Lambda provides the following runtimes for .NET languages:

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
.NET 10	dotnet10	Amazon Linux 2023	Nov 14, 2028	Dec 14, 2028	Jan 15, 2029
.NET 9 (container only)	dotnet9	Amazon Linux 2023	Nov 10, 2026	Not scheduled	Not scheduled
.NET 8	dotnet8	Amazon Linux 2023	Nov 10, 2026	Dec 10, 2026	Jan 11, 2027

Setting up your .NET development environment

To develop and build your Lambda functions, you can use any of the commonly available .NET integrated development environments (IDEs), including Microsoft Visual Studio, Visual Studio Code, and JetBrains Rider. To simplify your development experience, AWS provides a set of .NET project templates, as well as the Amazon.Lambda.Tools command line interface (CLI).

Run the following .NET CLI commands to install these project templates and command line tools.

Installing the .NET project templates

To install the project templates, run the following command:

```
dotnet new install Amazon.Lambda.Templates
```

Installing and updating the CLI tools

Run the following commands to install, update, and uninstall the Amazon.Lambda.Tools CLI.

To install the command line tools:

```
dotnet tool install -g Amazon.Lambda.Tools
```

To update the command line tools:

```
dotnet tool update -g Amazon.Lambda.Tools
```

To uninstall the command line tools:

```
dotnet tool uninstall -g Amazon.Lambda.Tools
```

Define Lambda function handler in C#

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in C# to work with the .NET managed runtime, including options for project setup, naming conventions, and best practices. This page also includes an example of a C# Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (S3) bucket. For information about how to deploy your function after writing it, see [the section called “Deployment package”](#) or [the section called “Deploy container images”](#).

Setting up your C# handler project

When working with Lambda functions in C#, the process involves writing your code, then deploying your code to Lambda. There are two different execution models for deploying Lambda functions in .NET: the class library approach and the executable assembly approach.

In the class library approach, you package your function code as a .NET assembly (.dll) and deploy it to Lambda with the .NET managed runtime (dotnet8). For the handler name, Lambda expects a string in the format `AssemblyName::Namespace.Classname::Methodname`. During the function's initialization phase, your function's class is initialized, and any code in the constructor is run.

In the executable assembly approach, you use the [top-level statements feature](#) that was first introduced in C# 9. This approach generates an executable assembly which Lambda runs whenever it receives an invoke command for your function. In this approach, you also use the .NET managed runtime (dotnet8). For the handler name, you provide Lambda with the name of the executable assembly to run.

The main example on this page illustrates the class library approach. You can initialize your C# Lambda project in various ways, but the easiest way is to use the .NET CLI with the `Amazon.Lambda.Tools` CLI. Set up the `Amazon.Lambda.Tools` CLI by following the steps in [the section called "Development environment"](#). Then, initialize your project with the following command:

```
dotnet new lambda.EmptyFunction --name ExampleCS
```

This command generates the following file structure:

```
/project-root
# src
# ExampleCS
#   Function.cs (contains main handler)
#   Readme.md
#   aws-lambda-tools-defaults.json
#   ExampleCS.csproj
# test
# ExampleCS.Tests
#   FunctionTest.cs (contains main handler)
#   ExampleCS.Tests.csproj
```

In this file structure, the main handler logic for your function resides in the `Function.cs` file.

Example C# Lambda function code

The following example C# Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket.

Example Function.cs Lambda function

```
using System;
using System.Text;
using System.Threading.Tasks;
using Amazon.Lambda.Core;
using Amazon.S3;
using Amazon.S3.Model;

// Assembly attribute to enable Lambda function logging
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))]

namespace ExampleLambda;

public class Order
{
    public string OrderId { get; set; } = string.Empty;
    public double Amount { get; set; }
    public string Item { get; set; } = string.Empty;
}

public class OrderHandler
{
    private static readonly AmazonS3Client s3Client = new();

    public async Task<string> HandleRequest(Order order, ILambdaContext context)
    {
        try
        {
            string? bucketName = Environment.GetEnvironmentVariable("RECEIPT_BUCKET");
            if (string.IsNullOrEmpty(bucketName))
            {
                throw new ArgumentException("RECEIPT_BUCKET environment variable is not set");
            }

            string receiptContent = $"OrderID: {order.OrderId}\nAmount:
            ${order.Amount:F2}\nItem: {order.Item}";
            string key = $"receipts/{order.OrderId}.txt";

            await UploadReceiptToS3(bucketName, key, receiptContent);
        }
    }
}
```

```

        context.Logger.LogInformation($"Successfully processed order
{order.OrderId} and stored receipt in S3 bucket {bucketName}");
        return "Success";
    }
    catch (Exception ex)
    {
        context.Logger.LogError($"Failed to process order: {ex.Message}");
        throw;
    }
}

private async Task UploadReceiptToS3(string bucketName, string key, string
receiptContent)
{
    try
    {
        var putRequest = new PutObjectRequest
        {
            BucketName = bucketName,
            Key = key,
            ContentBody = receiptContent,
            ContentType = "text/plain"
        };

        await s3Client.PutObjectAsync(putRequest);
    }
    catch (AmazonS3Exception ex)
    {
        throw new Exception($"Failed to upload receipt to S3: {ex.Message}", ex);
    }
}
}

```

This `Function.cs` file contains the following sections of code:

- **using statements:** Use these to import C# classes that your Lambda function requires.
- **[assembly: LambdaSerializer(...)]:** `LambdaSerializer` is an assembly attribute that tells Lambda to automatically convert JSON event payloads into C# objects before passing them to your function.
- **namespace ExampleLambda:** This defines the namespace. In C#, the namespace name doesn't have to match the filename.

- `public class Order {...}`: This defines the shape of the expected input event.
- `public class OrderHandler {...}`: This defines your C# class. Within it, you'll define the main handler method and any other helper methods.
- `private static readonly AmazonS3Client s3Client = new();`: This initializes an Amazon S3 client with the default credential provider chain, outside of the main handler method. This causes Lambda to run this code during the [initialization phase](#).
- `public async ... HandleRequest (Order order, ILambdaContext context)`: This is the **main handler method**, which contains your main application logic.
- `private async Task UploadReceiptToS3(...)` {}: This is a helper method that's referenced by the main `handleRequest` handler method.

Because this function requires an Amazon S3 SDK client, you must add it to your project's dependencies. You can do so by navigating to `src/ExampleCS` and running the following command:

```
dotnet add package AWSSDK.S3
```

Add metadata information to `aws-lambda-tools-defaults.json`

By default, the generated `aws-lambda-tools-defaults.json` file doesn't contain profile or region information for your function. In addition, update the `function-handler` string to the correct value (`ExampleCS::ExampleLambda.OrderHandler::HandleRequest`). You can manually make this update and add the necessary metadata to use a specific credentials profile and region for your function. For example, your `aws-lambda-tools-defaults.json` file should look similar to this:

```
{
  "Information": [
    "This file provides default values for the deployment wizard inside Visual Studio",
    "and the AWS Lambda commands added to the .NET Core CLI.",
    "To learn more about the Lambda commands with the .NET Core CLI execute the",
    "following command at the command line in the project root directory.",
    "dotnet lambda help",
    "All the command line options for the Lambda command can be specified in this",
    "file."
  ],
  "profile": "default",
  "region": "us-east-1",
```

```
"configuration": "Release",
"function-architecture": "x86_64",
"function-runtime": "dotnet8",
"function-memory-size": 512,
"function-timeout": 30,
"function-handler": "ExampleCS::ExampleLambda.OrderHandler::HandleRequest"
}
```

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

Class library handlers

The main [example code](#) on this page illustrates a class library handler. Class library handlers have the following structure:

```
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))

namespace NAMESPACE;

...

public class CLASSNAME {
    public async Task<string> METHODNAME (...) {
        ...
    }
}
```

When you create a Lambda function, you need to provide Lambda with information about your function's handler in the form of a string in the [Handler field](#). This tells Lambda which method in your code to run when your function is invoked. In C#, for class library handlers, the format of the handler string is `ASSEMBLY::TYPE::METHOD`, where:

- `ASSEMBLY` is the name of the .NET assembly file for your application. If you're using the `Amazon.Lambda.Tools` CLI to build your application and you don't set the assembly name using the `AssemblyName` property in the `.csproj` file, then `ASSEMBLY` is simply the name of your `.csproj` file.
- `TYPE` is the full name of the handler type, which is `NAMESPACE.CLASSNAME`.

- METHOD is the name of the main handler method in your code, which is METHODNAME.

For the main example code on this page, if the assembly is named `ExampleCS`, then the full handler string is `ExampleCS::ExampleLambda.OrderHandler::HandleRequest`.

Executable assembly handlers

You can also define Lambda functions in C# as an executable assembly. Executable assembly handlers utilize C#'s top-level statements feature, in which the compiler generates the `Main()` method and puts your function code within it. When using executable assemblies, the Lambda runtime must be bootstrapped. To do this, use the `LambdaBootstrapBuilder.Create` method in your code. The inputs to this method are the main handler function as well as the Lambda serializer to use. The following shows an example of an executable assembly handler in C#:

```
namespace GetProductHandler;

IDatabaseRepository repo = new DatabaseRepository();

await LambdaBootstrapBuilder.Create<APIGatewayProxyRequest>(Handler, new
    DefaultLambdaJsonSerializer())
    .Build()
    .RunAsync();

async Task<APIGatewayProxyResponse> Handler(APIGatewayProxyRequest apigProxyEvent,
    ILambdaContext context)
{
    var id = apigProxyEvent.PathParameters["id"];
    var databaseRecord = await this.repo.GetById(id);

    return new APIGatewayProxyResponse
    {
        StatusCode = (int)HttpStatusCode.OK,
        Body = JsonSerializer.Serialize(databaseRecord)
    };
};
```

In the [Handler field](#) for executable assembly handlers, the handler string that tells Lambda how to run your code is the name of the assembly. In this example, that's `GetProductHandler`.

Valid handler signatures for C# functions

In C#, valid Lambda handler signatures take between 0 and 2 arguments. Typically, your handler signature has two arguments, as shown in the main example:

```
public async Task<string> HandleRequest(Order order, ILambdaContext context)
```

When providing two arguments, the first argument must be the event input, and the second argument must be the Lambda context object. Both arguments are optional. For example, the following are also valid Lambda handler signatures in C#:

- `public async Task<string> HandleRequest()`
- `public async Task<string> HandleRequest(Order order)`
- `public async Task<string> HandleRequest(ILambdaContext context)`

Apart from the base syntax of the handler signature, there are some additional restrictions:

- You cannot use the `unsafe` keyword in the handler signature. However, you can use the `unsafe` context inside the handler method and its dependencies. For more information, see [unsafe \(C# reference\)](#) on the Microsoft documentation website.
- The handler may not use the `params` keyword, or use `ArgIterator` as an input or return parameter. These keywords support a variable number of parameters. The maximum number of arguments your handler can accept is two.
- The handler may not be a generic method. In other words, it can't use generic type parameters such as `<T>`.
- Lambda doesn't support async handlers with `async void` in the signature.

Handler naming conventions

Lambda handlers in C# don't have strict naming restrictions. However, you must ensure that you provide the correct handler string to Lambda when you deploy your function. The right handler string depends on if you're deploying a [class library handler](#) or an [executable assembly handler](#).

Although you can use any name for your handler, function names in C# are generally in PascalCase. Also, although the file name doesn't need to match the class name or handler name, it's generally

a best practice to use a filename like `OrderHandler.cs` if your class name is `OrderHandler`. For example, you can modify the file name in this example from `Function.cs` to `OrderHandler.cs`.

Serialization in C# Lambda functions

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "orderId": "12345",
  "amount": 199.99,
  "item": "Wireless Headphones"
}
```

In C#, you can define the shape of the expected input event in a class. In this example, we define the `Order` class to model this input:

```
public class Order
{
    public string OrderId { get; set; } = string.Empty;
    public double Amount { get; set; }
    public string Item { get; set; } = string.Empty;
}
```

If your Lambda function uses input or output types other than a `Stream` object, you must add a serialization library to your application. This lets you convert the JSON input into an instance of the class that you defined. There are two methods of serialization for C# functions in Lambda: reflection-based serialization and source-generated serialization.

Reflection-based serialization

AWS provides pre-built libraries that you can quickly add to your application. These libraries implement serialization using [reflection](#). Use one of the following packages to implement reflection-based serialization:

- `Amazon.Lambda.Serialization.SystemTextJson` – In the backend, this package uses `System.Text.Json` to perform serialization tasks.
- `Amazon.Lambda.Serialization.Json` – In the backend, this package uses `Newtonsoft.Json` to perform serialization tasks.

You can also create your own serialization library by implementing the `ILambdaSerializer` interface, which is available as part of the `Amazon.Lambda.Core` library. This interface defines two methods:

- `T Deserialize<T>(Stream requestStream);`

You implement this method to deserialize the request payload from the Invoke API into the object that is passed to your Lambda function handler.

- `T Serialize<T>(T response, Stream responseStream);`

You implement this method to serialize the result returned from your Lambda function handler into the response payload that the Invoke API operation returns.

The main example on this page uses reflection-based serialization. Reflection-based serialization works out of the box with AWS Lambda and requires no additional setup, making it a good choice for simplicity. However, it does require more function memory usage. You may also see higher function latencies due to runtime reflection.

Source-generated serialization

With source-generated serialization, serialization code is generated at compile time. This removes the need for reflection and can improve the performance of your function. To use source-generated serialization in your function, you must do the following:

- Create a new partial class that inherits from `JsonSerializerContext`, adding `JsonSerializable` attributes for all types that require serialization or deserialization.
- Configure the `LambdaSerializer` to use a `SourceGeneratorLambdaJsonSerializer<T>`.
- Update any manual serialization and deserialization in your application code to use the newly created class.

The following example shows how you can modify the main example on this page, which uses reflection-based serialization, to use source-generated serialization instead.

```
using System.Text.Json;
using System.Text.Json.Serialization;

...
```

```
public class Order
{
    public string OrderId { get; set; } = string.Empty;
    public double Amount { get; set; }
    public string Item { get; set; } = string.Empty;
}

[JsonSerializable(typeof(Order))]
public partial class OrderJsonContext : JsonSerializerContext {}

public class OrderHandler
{
    ...

    public async Task<string> HandleRequest(string input, ILambdaContext context)
    {
        var order = JsonSerializer.Deserialize(input, OrderJsonContext.Default.Order);

        ...
    }
}
```

Source-generated serialization requires more setup than reflection-based serialization. However, functions using source-generated tend to use less memory and have better performance due to compile-time code generation. To help eliminate function [cold starts](#), consider switching to source-generated serialization.

 **Note**

If you want to use native [ahead-of-time compilation \(AOT\)](#) with Lambda, you must use source-generated serialization.

File-based functions

Introduced in .NET 10, file-based apps enable you to build .NET applications from a single .cs file, without a .csproj file or directory structure. Lambda supports file-based functions, starting with .NET 10. They offer a streamlined, lightweight way to build Lambda functions in C#.

The fastest way to get started creating a C# file-based Lambda function is to use the `Amazon.Lambda.Templates` package. To install the package, run the following command:

```
dotnet new install Amazon.Lambda.Templates
```

Next, create a C# file-based Lambda example function:

```
dotnet new lambda.FileBased -n MyLambdaFunction
```

File-based functions use [executable assembly handlers](#). You must therefore include the `Amazon.Lambda.RuntimeSupport` NuGet package and use the `LambdaBootstrapBuilder.Create` method to register the .NET handler function for the event type and start the .NET Lambda runtime client.

File-based functions use .NET Native AOT by default, which requires source-generated serialization. You can disable Native AOT by specifying `#:property PublishAot=false` in your source file. For more information on using Native AOT in Lambda, see [the section called “Native AOT compilation”](#).

Accessing and using the Lambda context object

The Lambda [context object](#) contains information about the invocation, function, and execution environment. In this example, the context object is of type `Amazon.Lambda.Core.ILambdaContext`, and is the second argument of the main handler function.

```
public async Task<string> HandleRequest(Order order, ILambdaContext context) {  
    ...  
}
```

The context object is an optional input. For more information about valid accepted handler signatures, see [the section called “Valid handler signatures for C# functions”](#).

The context object is useful for producing function logs to Amazon CloudWatch. You can use the `context.getLogger()` method to get a `LambdaLogger` object for logging. In this example, we can use the logger to log an error message if processing fails for any reason:

```
context.Logger.LogError($"Failed to process order: {ex.Message}");
```

Outside of logging, you can also use the context object for function monitoring. For more information about the context object, see [the section called "Context"](#).

Using the SDK for .NET v3 in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the SDK for .NET v3.

Note

The SDK for .NET (v2) is deprecated. We recommend that you use only the SDK for .NET v3.

You can add SDK dependencies to your project using the following `Amazon.Lambda.Tools` command:

```
dotnet add package <package_name>
```

For example, in the main example on this page, we need to use the Amazon S3 API to upload a receipt to S3. We can import the Amazon S3 SDK client with the following command:

```
dotnet add package AWSSDK.S3
```

This command adds the dependency to your project. You should also see a line similar to the following in your project's `.csproj` file:

```
<PackageReference Include="AWSSDK.S3" Version="3.7.2.18" />
```

Then, import the dependencies directly in your C# code:

```
using Amazon.S3;
```

```
using Amazon.S3.Model;
```

The example code then initializes an Amazon S3 client (using the [default credential provider chain](#)) as follows:

```
private static readonly AmazonS3Client s3Client = new();
```

In this example, we initialized our Amazon S3 client outside of the main handler function to avoid having to initialize it every time we invoke our function. After you initialize your SDK client, you can then use it to interact with other AWS services. The example code calls the Amazon S3 `PutObject` API as follows:

```
var putRequest = new PutObjectRequest
{
    BucketName = bucketName,
    Key = key,
    ContentBody = receiptContent,
    ContentType = "text/plain"
};

await s3Client.PutObjectAsync(putRequest);
```

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using the `System.Environment.GetEnvironmentVariable` method. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following lines of code:

```
string? bucketName = Environment.GetEnvironmentVariable("RECEIPT_BUCKET");
if (string.IsNullOrEmpty(bucketName))
{
    throw new ArgumentException("RECEIPT_BUCKET environment variable is not set");
}
```

Using global state

Lambda runs your static code and the class constructor during the [initialization phase](#) before invoking your function for the first time. Resources created during initialization stay in memory between invocations, so you can avoid having to create them every time you invoke your function.

In the example code, the S3 client initialization code is outside the main handler method. The runtime initializes the client before the function handles its first event, which can lead to longer processing times. Subsequent events are much faster because Lambda doesn't need to initialize the client again.

Simplify function code with the Lambda Annotations framework

[Lambda Annotations](#) is a framework for .NET 8 which simplifies writing Lambda functions using C#. The Annotations framework uses [source generators](#) to generate code that translates from the Lambda programming model to the simplified code. With the Annotations framework, you can replace much of the code in a Lambda function written using the regular programming model. Code written using the framework uses simpler expressions that allow you to focus on your business logic. See [Amazon.Lambda.Annotations](#) in the nuget documentation for examples.

For an example of a full application utilizing Lambda Annotations, see the [PhotoAssetManager](#) example in the `awsdocs/aws-doc-sdk-examples` GitHub repository. The main `Function.cs` file in the `PamApiAnnotations` directory uses Lambda Annotations. For comparison, the `PamApi` directory has equivalent files written using the regular Lambda programming model.

Dependency injection with Lambda Annotations framework

You can also use the Lambda Annotations framework to add dependency injection to your Lambda functions using syntax you are familiar with. When you add a `[LambdaStartup]` attribute to a `Startup.cs` file, the Lambda Annotations framework will generate the required code at compile time.

```
[LambdaStartup]
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddSingleton<IDatabaseRepository, DatabaseRepository>();
    }
}
```

Your Lambda function can inject services using either constructor injection or by injecting into individual methods using the `[FromServices]` attribute.

```
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))

namespace GetProductHandler;

public class Function
{
    private readonly IDatabaseRepository _repo;

    public Function(IDatabaseRepository repo)
    {
        this._repo = repo;
    }

    [LambdaFunction]
    [HttpApi(LambdaHttpMethod.Get, "/product/{id}")]
    public async Task<Product> FunctionHandler([FromServices] IDatabaseRepository
repository, string id)
    {
        return await this._repo.GetById(id);
    }
}
```

Code best practices for C# Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Control the dependencies in your function's deployment package.** The AWS Lambda execution environment contains a number of libraries. To enable the latest set of features and security updates, Lambda will periodically update these libraries. These updates may introduce subtle changes to the behavior of your Lambda function. To have full control of the dependencies your function uses, package all of your dependencies with your deployment package.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked

ahead of invocation. For functions authored in .NET, avoid uploading the entire AWS SDK library as part of your deployment package. Instead, selectively depend on the modules which pick up components of the SDK you need (e.g. DynamoDB, Amazon S3 SDK modules and Lambda core libraries).

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Build and deploy C# Lambda functions with .zip file archives

A .NET deployment package (.zip file archive) contains your function's compiled assembly along with all of its assembly dependencies. The package also contains a `proj.deps.json` file. This signals to the .NET runtime all of your function's dependencies and a `proj.runtimeconfig.json` file, which is used to configure the runtime.

To deploy individual Lambda functions, you can use the `Amazon.Lambda.Tools .NET Lambda Global CLI`. Using the `dotnet lambda deploy-function` command automatically creates a .zip deployment package and deploys it to Lambda. However, we recommend that you use frameworks like the AWS Serverless Application Model (AWS SAM) or the AWS Cloud Development Kit (AWS CDK) to deploy your .NET applications to AWS.

Serverless applications usually comprise a combination of Lambda functions and other managed AWS services working together to perform a particular business task. AWS SAM and AWS CDK simplify building and deploying Lambda functions with other AWS services at scale. The [AWS SAM template specification](#) provides a simple and clean syntax to describe Lambda functions, APIs, permissions, configurations, and other AWS resources that make up your serverless application. With the [AWS CDK](#) you define cloud infrastructure as code to help you build reliable, scalable, cost-effective applications in the cloud using modern programming languages and frameworks like .NET. Both the AWS CDK and the AWS SAM use the .NET Lambda Global CLI to package your functions.

While it's possible to use [Lambda layers](#) with functions in C# by [using the .NET Core CLI](#), we recommend against it. Functions in C# that use layers manually load the shared assemblies into memory during the [Init phase](#), which can increase cold start times. Instead, include all shared code at compile time to avoid the performance impact of loading assemblies at runtime.

You can find instructions for building and deploying .NET Lambda functions using the AWS SAM, the AWS CDK, and the .NET Lambda Global CLI in the following sections.

Topics

- [Using the .NET Lambda Global CLI](#)
- [Deploy C# Lambda functions using AWS SAM](#)
- [Deploy C# Lambda functions using AWS CDK](#)
- [Deploy ASP.NET applications](#)

Using the .NET Lambda Global CLI

The .NET CLI and the .NET Lambda Global Tools extension (`Amazon.Lambda.Tools`) offer a cross-platform way to create .NET-based Lambda applications, package them, and deploy them to Lambda. In this section, you learn how to create new Lambda .NET projects using the .NET CLI and Amazon Lambda templates, and to package and deploy them using `Amazon.Lambda.Tools`

Topics

- [Prerequisites](#)
- [Creating .NET projects using the .NET CLI](#)
- [Deploying .NET projects using the .NET CLI](#)
- [Using Lambda layers with the .NET CLI](#)

Prerequisites

.NET 8 SDK

If you haven't already done so, install the [.NET 8](#) SDK and Runtime.

AWS `Amazon.Lambda.Templates` .NET project templates

To generate your Lambda function code, use the [Amazon.Lambda.Templates](#) NuGet package. To install this template package, run the following command:

```
dotnet new install Amazon.Lambda.Templates
```

AWS `Amazon.Lambda.Tools` .NET Global CLI tools

To create your Lambda functions, you use the [Amazon.Lambda.Tools .NET Global Tools extension](#). To install `Amazon.Lambda.Tools`, run the following command:

```
dotnet tool install -g Amazon.Lambda.Tools
```

For more information about the `Amazon.Lambda.Tools` .NET CLI extension, see the [AWS Extensions for .NET CLI](#) repository on GitHub.

Creating .NET projects using the .NET CLI

In the .NET CLI, you use the `dotnet new` command to create .NET projects from the command line. Lambda offers additional templates using the [Amazon.Lambda.Templates](#) NuGet package.

After installing this package, run the following command to see a list of the available templates.

```
dotnet new list
```

To examine details about a template, use the `help` option. For example, to see details about the `lambda.EmptyFunction` template, run the following command.

```
dotnet new lambda.EmptyFunction --help
```

To create a basic template for a .NET Lambda function, use the `lambda.EmptyFunction` template. This creates a simple function that takes a string as input and converts it to upper case using the `ToUpper` method. This template supports the following options:

- `--name` – The name of the function.
- `--region` – The AWS Region to create the function in.
- `--profile` – The name of a profile in your AWS SDK for .NET credentials file. To learn more about credential profiles in .NET, see [Configure AWS credentials](#) in the *AWS SDK for .NET Developer Guide*.

In this example, we create a new empty function named `myDotnetFunction` using the default profile and AWS Region settings:

```
dotnet new lambda.EmptyFunction --name myDotnetFunction
```

This command creates the following files and directories in your project directory.

```
### myDotnetFunction
### src
#   ### myDotnetFunction
#       ### Function.cs
#       ### Readme.md
#       ### aws-lambda-tools-defaults.json
#       ### myDotnetFunction.csproj
```

```

### test
### myDotnetFunction.Tests
### FunctionTest.cs
### myDotnetFunction.Tests.csproj

```

Under the `src/myDotnetFunction` directory, examine the following files:

- **aws-lambda-tools-defaults.json:** This is where you specify the command line options when deploying your Lambda function. For example:

```

"profile" : "default",
"region" : "us-east-2",
"configuration" : "Release",
"function-architecture": "x86_64",
"function-runtime":"dotnet8",
"function-memory-size" : 256,
"function-timeout" : 30,
"function-handler" : "myDotnetFunction::myDotnetFunction.Function::FunctionHandler"

```

- **Function.cs:** Your Lambda handler function code. It's a C# template that includes the default `Amazon.Lambda.Core` library and a default `LambdaSerializer` attribute. For more information on serialization requirements and options, see [Serialization in C# Lambda functions](#). It also includes a sample function that you can edit to apply your Lambda function code.

```

using Amazon.Lambda.Core;

// Assembly attribute to enable the Lambda function's JSON input to be converted into
// a .NET class.
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))]

namespace myDotnetFunction;

public class Function
{
    /// <summary>
    /// A simple function that takes a string and does a ToUpper
    /// </summary>
    /// <param name="input"></param>
    /// <param name="context"></param>
    /// <returns></returns>

```

```
public string FunctionHandler(string input, ILambdaContext context)
{
    return input.ToUpper();
}
}
```

- **myDotnetFunction.csproj:** An [MSBuild](#) file that lists the files and assemblies that comprise your application.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <ImplicitUsings>enable</ImplicitUsings>
    <Nullable>enable</Nullable>
    <GenerateRuntimeConfigurationFiles>true</GenerateRuntimeConfigurationFiles>
    <AWSProjectType>Lambda</AWSProjectType>
    <!-- This property makes the build directory similar to a publish directory and
helps the AWS .NET Lambda Mock Test Tool find project dependencies. -->
    <CopyLocalLockFileAssemblies>true</CopyLocalLockFileAssemblies>
    <!-- Generate ready to run images during publishing to improve cold start time.
-->
    <PublishReadyToRun>true</PublishReadyToRun>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Amazon.Lambda.Core" Version="2.2.0" />
    <PackageReference Include="Amazon.Lambda.Serialization.SystemTextJson"
Version="2.4.0" />
  </ItemGroup>
</Project>
```

- **Readme:** Use this file to document your Lambda function.

Under the myfunction/test directory, examine the following files:

- **myDotnetFunction.Tests.csproj:** As noted previously, this is an [MSBuild](#) file that lists the files and assemblies that comprise your test project. Note also that it includes the `Amazon.Lambda.Core` library, so you can seamlessly integrate any Lambda templates required to test your function.

```
<Project Sdk="Microsoft.NET.Sdk">
  ...
```

```
<PackageReference Include="Amazon.Lambda.Core" Version="2.2.0 " />
...
```

- **FunctionTest.cs:** The same C# code template file that it is included in the src directory. Edit this file to mirror your function's production code and test it before uploading your Lambda function to a production environment.

```
using Xunit;
using Amazon.Lambda.Core;
using Amazon.Lambda.TestUtilities;

using MyFunction;

namespace MyFunction.Tests
{
    public class FunctionTest
    {
        [Fact]
        public void TestToUpperFunction()
        {
            // Invoke the lambda function and confirm the string was upper cased.
            var function = new Function();
            var context = new TestLambdaContext();
            var upperCase = function.FunctionHandler("hello world", context);

            Assert.Equal("HELLO WORLD", upperCase);
        }
    }
}
```

Deploying .NET projects using the .NET CLI

To build your deployment package and deploy it to Lambda, you use the `Amazon.Lambda.Tools` CLI tools. To deploy your function from the files you created in the previous steps, first navigate into the folder containing your function's `.csproj` file.

```
cd myDotnetFunction/src/myDotnetFunction
```

To deploy your code to Lambda as a `.zip` deployment package, run the following command. Choose your own function name.

```
dotnet lambda deploy-function myDotnetFunction
```

During the deployment, the wizard asks you to select a [the section called “Execution role \(permissions for functions to access other resources\)”](#). For this example, select the `lambda_basic_role`.

After you have deployed your function, you can test it in the cloud using the `dotnet lambda invoke-function` command. For the example code in the `lambda.EmptyFunction` template, you can test your function by passing in a string using the `--payload` option.

```
dotnet lambda invoke-function myDotnetFunction --payload "Just checking if everything  
is OK"
```

If your function has been successfully deployed, you should see output similar to the following.

```
dotnet lambda invoke-function myDotnetFunction --payload "Just checking if everything  
is OK"  
Amazon Lambda Tools for .NET Core applications (5.8.0)  
Project Home: https://github.com/aws/aws-extensions-for-dotnet-cli, https://github.com/  
aws/aws-lambda-dotnet  
  
Payload:  
"JUST CHECKING IF EVERYTHING IS OK"  
  
Log Tail:  
START RequestId: id Version: $LATEST  
END RequestId: id  
REPORT RequestId: id Duration: 0.99 ms          Billed Duration: 1 ms          Memory  
Size: 256 MB          Max Memory Used: 12 MB
```

Using Lambda layers with the .NET CLI

Note

While it's possible to use [layers](#) with functions in .NET, we recommend against it. Functions in .NET that use layers manually load the shared assemblies into memory during the `Init` phase, which can increase cold start times. Instead, include all shared code at compile time to take advantage of the built-in optimizations of the .NET compiler.

The .NET CLI supports commands to help you publish layers and deploy C# functions that consume layers. To publish a layer to a specified Amazon S3 bucket, run the following command in the same directory as your `.csproj` file:

```
dotnet lambda publish-layer <layer_name> --layer-type runtime-package-store --s3-bucket <s3_bucket_name>
```

Then, when you deploy your function using the .NET CLI, specify the layer ARN the consume in the following command:

```
dotnet lambda deploy-function <function_name> --function-layers arn:aws:lambda:us-east-1:123456789012:layer:layer-name:1
```

For a complete example of a Hello World function, see the [blank-csharp-with-layer](#) sample.

Deploy C# Lambda functions using AWS SAM

The AWS Serverless Application Model (AWS SAM) is a toolkit that helps streamline the process of building and running serverless applications on AWS. You define the resources for your application in a YAML or JSON template and use the AWS SAM command line interface (AWS SAM CLI) to build, package, and deploy your applications. When you build a Lambda function from an AWS SAM template, AWS SAM automatically creates a .zip deployment package or container image with your function code and any dependencies you specify. AWS SAM then deploys your function using an [CloudFormation stack](#). To learn more about using AWS SAM to build and deploy Lambda functions, see [Getting started with AWS SAM](#) in the *AWS Serverless Application Model Developer Guide*.

The following steps show you how to download, build, and deploy a sample .NET Hello World application using AWS SAM. This sample application uses a Lambda function and an Amazon API Gateway endpoint to implement a basic API backend. When you send an HTTP GET request to your API Gateway endpoint, API Gateway invokes your Lambda function. The function returns a "hello world" message, along with the IP address of the Lambda function instance that processes your request.

When you build and deploy your application using AWS SAM, behind the scenes the AWS SAM CLI uses the `dotnet lambda package` command to package the individual Lambda function code bundles.

Prerequisites

.NET 8 SDK

Install the [.NET 8](#) SDK and Runtime.

AWS SAM CLI version 1.39 or later

To learn how to install the latest version of the AWS SAM CLI, see [Installing the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello world .NET template using the following command.

```
sam init --app-template hello-world --name sam-app \
--package-type Zip --runtime dotnet8
```

This command creates the following files and directories in your project directory.

```
### sam-app
### README.md
### events
#   ### event.json
### omnisharp.json
### samconfig.toml
### src
#   ### HelloWorld
#       ### Function.cs
#       ### HelloWorld.csproj
#       ### aws-lambda-tools-defaults.json
### template.yaml
### test
### HelloWorld.Test
### FunctionTest.cs
### HelloWorld.Tests.csproj
```

2. Navigate into the directory containing the `template.yaml` file. This file is a template that defines the AWS resources for your application, including your Lambda function and an API Gateway API.

```
cd sam-app
```

3. To build the source of your application, run the following command.

```
sam build
```

4. To deploy your application to AWS, run the following command.

```
sam deploy --guided
```

This command packages and deploys your application with the following series of prompts. To accept the default options, press Enter.

 **Note**

For **HelloWorldFunction may not have authorization defined, is this okay?**, be sure to enter y.

- **Stack Name:** The name of the stack to deploy to CloudFormation. This name must be unique to your AWS account and AWS Region.
 - **AWS Region:** The AWS Region you want to deploy your app to.
 - **Confirm changes before deploy:** Select yes to manually review any change sets before AWS SAM deploys application changes. If you select no, the AWS SAM CLI automatically deploys application changes.
 - **Allow SAM CLI IAM role creation:** Many AWS SAM templates, including the Hello world one in this example, create AWS Identity and Access Management (IAM) roles to give your Lambda functions permission to access other AWS services. Select Yes to provide permission to deploy a CloudFormation stack that creates or modifies IAM roles.
 - **Disable rollback:** By default, if AWS SAM encounters an error during creation or deployment of your stack, it rolls the stack back to the previous version. Select No to accept this default.
 - **HelloWorldFunction may not have authorization defined, is this okay:** Enter y.
 - **Save arguments to samconfig.toml:** Select yes to save your configuration choices. In the future, you can re-run `sam deploy` without parameters to deploy changes to your application.
5. When the deployment of your application is complete, the CLI returns the Amazon Resource Name (ARN) of the Hello World Lambda function and the IAM role created for it. It also

displays the endpoint of your API Gateway API. To test your application, open the endpoint in a browser. You should see a response similar to the following.

```
{"message":"hello world","location":"34.244.135.203"}
```

6. To delete your resources, run the following command. Note that the API endpoint you created is a public endpoint accessible over the internet. We recommend that you delete this endpoint after testing.

```
sam delete
```

Next steps

To learn more about using AWS SAM to build and deploy Lambda functions using .NET, see the following resources:

- The [AWS Serverless Application Model \(AWS SAM\) Developer Guide](#)
- [Building Serverless .NET Applications with AWS Lambda and the SAM CLI](#)

Deploy C# Lambda functions using AWS CDK

The AWS Cloud Development Kit (AWS CDK) is an open-source software development framework for defining cloud infrastructure as code with modern programming languages and frameworks like .NET. AWS CDK projects are executed to generate CloudFormation templates which are then used to deploy your code.

To build and deploy an example Hello world .NET application using the AWS CDK, follow the instructions in the following sections. The sample application implements a basic API backend consisting of an API Gateway endpoint and a Lambda function. API Gateway invokes the Lambda function when you send an HTTP GET request to the endpoint. The function returns a Hello world message, along with the IP address of the Lambda instance that processes your request.

Prerequisites

.NET 8 SDK

Install the [.NET 8](#) SDK and Runtime.

AWS CDK version 2

To learn how to install the latest version of the AWS CDK see [Getting started with the AWS CDK](#) in the *AWS Cloud Development Kit (AWS CDK) v2 Developer Guide*.

Deploy a sample AWS CDK application

1. Create a project directory for the sample application and navigate into it.

```
mkdir hello-world
cd hello-world
```

2. Initialize a new AWS CDK application by running the following command.

```
cdk init app --language csharp
```

The command creates the following files and directories in your project directory

```
### README.md
### cdk.json
### src
    ### HelloWorld
    #   ### GlobalSuppressions.cs
    #   ### HelloWorld.csproj
    #   ### HelloWorldStack.cs
    #   ### Program.cs
    ### HelloWorld.sln
```

3. Open the `src` directory and create a new Lambda function using the .NET CLI. This is the function you will deploy using the AWS CDK. In this example, you create a Hello world function named `HelloWorldLambda` using the `lambda.EmptyFunction` template.

```
cd src
dotnet new lambda.EmptyFunction -n HelloWorldLambda
```

After this step, your directory structure inside your project directory should look like the following.

```
### README.md
### cdk.json
```

```

### src
### HelloWorld
#   ### GlobalSuppressions.cs
#   ### HelloWorld.csproj
#   ### HelloWorldStack.cs
#   ### Program.cs
### HelloWorld.sln
### HelloWorldLambda
    ### src
    #   ### HelloWorldLambda
    #   ### Function.cs
    #   ### HelloWorldLambda.csproj
    #   ### Readme.md
    #   ### aws-lambda-tools-defaults.json
### test
    ### HelloWorldLambda.Tests
    ### FunctionTest.cs
    ### HelloWorldLambda.Tests.csproj

```

4. Open the `HelloWorldStack.cs` file from the `src/HelloWorld` directory. Replace the contents of the file with the following code.

```

using Amazon.CDK;
using Amazon.CDK.AWS.Lambda;
using Amazon.CDK.AWS.Logs;
using Constructs;

namespace CdkTest
{
    public class HelloWorldStack : Stack
    {
        internal HelloWorldStack(Construct scope, string id, IStackProps props =
null) : base(scope, id, props)
        {
            var buildOption = new BundlingOptions()
            {
                Image = Runtime.DOTNET_8.BundlingImage,
                User = "root",
                OutputType = BundlingOutput.ARCHIVED,
                Command = new string[]{
                    "/bin/sh",
                    "-c",
                    "dotnet tool install -g Amazon.Lambda.Tools"+

```

```

        " && dotnet build"+
        " && dotnet lambda package --output-package /asset-output/"
function.zip"
    }
};

var helloWorldLambdaFunction = new Function(this,
"HelloWorldFunction", new FunctionProps
{
    Runtime = Runtime.DOTNET_8,
    MemorySize = 1024,
    LogRetention = RetentionDays.ONE_DAY,
    Handler =
    "HelloWorldLambda::HelloWorldLambda.Function::FunctionHandler",
    Code = Code.FromAsset("./src/HelloWorldLambda/src/
HelloWorldLambda", new Amazon.CDK.AWS.S3.Assets.AssetOptions
    {
        Bundling = buildOption
    }),
});
}
}
}
}

```

This is the code to compile and bundle the application code, as well as the definition of the Lambda function itself. the `BundlingOptions` object allows a zip file to be created, along with a set of commands that are used to generate the contents of the zip file. In this instance, the `dotnet lambda package` command is used to compile and generate the zip file.

5. To deploy your application, run the following command.

```
cdk deploy
```

6. Invoke your deployed Lambda function using the .NET Lambda CLI.

```
dotnet lambda invoke-function HelloWorldFunction -p "hello world"
```

7. After you've finished testing, you can delete the resources you created, unless you want to retain them. Run the following command to delete your resources.

```
cdk destroy
```

Next steps

To learn more about using AWS CDK to build and deploy Lambda functions using .NET, see the following resources:

- [Working with the AWS CDK in C#](#)
- [Build, package, and publish .NET C# Lambda functions with the AWS CDK](#)

Deploy ASP.NET applications

As well as hosting event-driven functions, you can also use .NET with Lambda to host lightweight ASP.NET applications. You can build and deploy ASP.NET applications using the `Amazon.Lambda.AspNetCoreServer` NuGet package. In this section, you learn how to deploy an ASP.NET web API to Lambda using the .NET Lambda CLI tooling.

Topics

- [Prerequisites](#)
- [Deploying an ASP.NET Web API to Lambda](#)
- [Deploying ASP.NET minimal APIs to Lambda](#)

Prerequisites

.NET 8 SDK

Install the [.NET 8](#) SDK and ASP.NET Core Runtime.

Amazon.Lambda.Tools

To create your Lambda functions, you use the [Amazon.Lambda.Tools .NET Global Tools extension](#). To install `Amazon.Lambda.Tools`, run the following command:

```
dotnet tool install -g Amazon.Lambda.Tools
```

For more information about the `Amazon.Lambda.Tools` .NET CLI extension, see the [AWS Extensions for .NET CLI](#) repository on GitHub.

Amazon.Lambda.Templates

To generate your Lambda function code, use the [Amazon.Lambda.Templates](#) NuGet package. To install this template package, run the following command:

```
dotnet new --install Amazon.Lambda.Templates
```

Deploying an ASP.NET Web API to Lambda

To deploy a web API using ASP.NET, you can use the .NET Lambda templates to create a new web API project. Use the following command to initialize a new ASP.NET web API project. In the example command, we name the project `AspNetOnLambda`.

```
dotnet new serverless.AspNetCoreWebAPI -n AspNetOnLambda
```

This command creates the following files and directories in your project directory.

```
.
### AspNetOnLambda
  ### src
    #   ### AspNetOnLambda
    #     ### AspNetOnLambda.csproj
    #     ### Controllers
    #     #   ### ValuesController.cs
    #     ### LambdaEntryPoint.cs
    #     ### LocalEntryPoint.cs
    #     ### Readme.md
    #     ### Startup.cs
    #     ### appsettings.Development.json
    #     ### appsettings.json
    #     ### aws-lambda-tools-defaults.json
    #     ### serverless.template
  ### test
    ### AspNetOnLambda.Tests
      ### AspNetOnLambda.Tests.csproj
      ### SampleRequests
      #   ### ValuesController-Get.json
      ### ValuesControllerTests.cs
      ### appsettings.json
```

When Lambda invokes your function, the entry point it uses is the `LambdaEntryPoint.cs` file. The file created by the .NET Lambda template contains the following code.

```
namespace AspNetOnLambda;
```

```
public class LambdaEntryPoint : Amazon.Lambda.AspNetCoreServer.APIGatewayProxyFunction
{
    protected override void Init(IWebHostBuilder builder)
    {
        builder
            .UseStartup#Startup#();
    }

    protected override void Init(IHostBuilder builder)
    {
    }
}
```

The entry point used by Lambda must inherit from one of the three base classes in the `Amazon.Lambda.AspNetCoreServer` package. These three base classes are:

- `APIGatewayProxyFunction`
- `APIGatewayHttpApiV2ProxyFunction`
- `ApplicationLoadBalancerFunction`

The default class used when you create your `LambdaEntryPoint.cs` file using the provided .NET Lambda template is `APIGatewayProxyFunction`. The base class you use in your function depends on which API layer sits in front of your Lambda function.

Each of the three base classes contains a public method named `FunctionHandlerAsync`. The name of this method will form part of the [handler string](#) Lambda uses to invoke your function. The `FunctionHandlerAsync` method transforms the inbound event payload into the correct ASP.NET format and the ASP.NET response back to a Lambda response payload. For the example `AspNetOnLambda` project shown, the handler string would be as follows.

```
AspNetOnLambda::AspNetOnLambda.LambdaEntryPoint::FunctionHandlerAsync
```

To deploy the API to Lambda, run the following commands to navigate into the directory containing your source code file and deploy your function using CloudFormation.

```
cd AspNetOnLambda/src/AspNetOnLambda
dotnet lambda deploy-serverless
```

Tip

When you deploy an API using the **dotnet lambda deploy-serverless** command, CloudFormation gives your Lambda function a name based on the stack name you specify during the deployment. To give your Lambda function a custom name, edit the `serverless.template` file to add a `FunctionName` property to the `AWS::Serverless::Function` resource. See [Name type](#) in the *CloudFormation User Guide* to learn more.

Deploying ASP.NET minimal APIs to Lambda

To deploy an ASP.NET minimal API to Lambda, you can use the .NET Lambda templates to create a new minimal API project. Use the following command to initialize a new minimal API project. In this example, we name the project `MinimalApiOnLambda`.

```
dotnet new serverless.AspNetCoreMinimalAPI -n MinimalApiOnLambda
```

The command creates the following files and directories in your project directory.

```
### MinimalApiOnLambda
  ### src
    ### MinimalApiOnLambda
      ### Controllers
      #   ### CalculatorController.cs
      ### MinimalApiOnLambda.csproj
      ### Program.cs
      ### Readme.md
      ### appsettings.Development.json
      ### appsettings.json
      ### aws-lambda-tools-defaults.json
      ### serverless.template
```

The `Program.cs` file contains the following code.

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddControllers();
```

```
// Add AWS Lambda support. When application is run in Lambda Kestrel is swapped out as
// the web server with Amazon.Lambda.AspNetCoreServer. This
// package will act as the webserver translating request and responses between the
// Lambda event source and ASP.NET Core.
builder.Services.AddAWSLambdaHosting(LambdaEventSource.RestApi);

var app = builder.Build();

app.UseHttpsRedirection();
app.UseAuthorization();
app.MapControllers();

app.MapGet("/", () => "Welcome to running ASP.NET Core Minimal API on AWS Lambda");

app.Run();
```

To configure your minimal API to run on Lambda, you may need to edit this code so that requests and responses between Lambda and ASP.NET Core are properly translated. By default, the function is configured for a REST API event source. For an HTTP API or application load balancer, replace (*LambdaEventSource.RestApi*) with one of the following options:

- (*LambdaEventSource.HttpApi*)
- (*LambdaEventSource.ApplicationLoadBalancer*)

To deploy your minimal API to Lambda, run the following commands to navigate into the directory containing your source code file and deploy your function using CloudFormation.

```
cd MinimalApiOnLambda/src/MinimalApiOnLambda
dotnet lambda deploy-serverless
```

Working with layers for .NET Lambda functions

We don't recommend using [layers](#) to manage dependencies for Lambda functions written in .NET. This is because .NET is a compiled language, and your functions still have to manually load any shared assemblies into memory during the [Init](#) phase, which can increase cold start times. Using layers not only complicates the deployment process, but also prevents you from taking advantage of built-in compiler optimizations.

To use external dependencies with your .NET handlers, include them directly in your deployment package at compile time. By doing so, you simplify the deployment process and also take advantage of built-in .NET compiler optimizations. For an example of how to import and use dependencies like NuGet packages in your function, see [the section called "Handler"](#).

Deploy .NET Lambda functions with container images

There are three ways to build a container image for a .NET Lambda function:

- [Using an AWS base image for .NET](#)

The [AWS base images](#) are preloaded with a language runtime, a runtime interface client to manage the interaction between Lambda and your function code, and a runtime interface emulator for local testing.

- [Using an AWS OS-only base image](#)

[AWS OS-only base images](#) contain an Amazon Linux distribution and the [runtime interface emulator](#). These images are commonly used to create container images for compiled languages, such as [Go](#) and [Rust](#), and for a language or language version that Lambda doesn't provide a base image for, such as Node.js 19. You can also use OS-only base images to implement a [custom runtime](#). To make the image compatible with Lambda, you must include the [the runtime interface client for .NET](#) in the image.

- [Using a non-AWS base image](#)

You can use an alternative base image from another container registry, such as Alpine Linux or Debian. You can also use a custom image created by your organization. To make the image compatible with Lambda, you must include the [the runtime interface client for .NET](#) in the image.

Tip

To reduce the time it takes for Lambda container functions to become active, see [Use multi-stage builds](#) in the Docker documentation. To build efficient container images, follow the [Best practices for writing Dockerfiles](#).

This page explains how to build, test, and deploy container images for Lambda.

Topics

- [AWS base images for .NET](#)
- [Using an AWS base image for .NET](#)
- [Using an alternative base image with the runtime interface client](#)

AWS base images for .NET

AWS provides the following base images for .NET:

Tags	Runtime	Operating system	Dockerfile	Deprecation
10	.NET 10	Amazon Linux 2023	Dockerfile for .NET 10 on GitHub	Nov 14, 2028
9	.NET 9	Amazon Linux 2023	Dockerfile for .NET 9 on GitHub	Nov 10, 2026
8	.NET 8	Amazon Linux 2023	Dockerfile for .NET 8 on GitHub	Nov 10, 2026

Amazon ECR repository: gallery.ecr.aws/lambda/dotnet

Using an AWS base image for .NET

Prerequisites

To complete the steps in this section, you must have the following:

- [.NET SDK](#) – The following steps use the .NET 8 base image. Make sure that your .NET version matches the version of the [base image](#) that you specify in your Dockerfile.
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).

Creating and deploying an image using a base image

In the following steps, you use [Amazon.Lambda.Templates](#) and [Amazon.Lambda.Tools](#) to create a .NET project. Then, you build a Docker image, upload the image to Amazon ECR, and deploy it to a Lambda function.

1. Install the [Amazon.Lambda.Templates](#) NuGet package.

```
dotnet new install Amazon.Lambda.Templates
```

2. Create a .NET project using the `lambda.image.EmptyFunction` template.

```
dotnet new lambda.image.EmptyFunction --name MyFunction --region us-east-1
```

The project files are stored in the *MyFunction*/src/*MyFunction* directory:

- **aws-lambda-tools-defaults.json:** Specifies the command line options for deploying your Lambda function.
- **Function.cs:** Your Lambda handler function code. This is a C# template that includes the default `Amazon.Lambda.Core` library and a default `LambdaSerializer` attribute. For more information about serialization requirements and options, see [Serialization in C# Lambda functions](#). You can use the provided code for testing, or replace it with your own.
- **MyFunction.csproj:** A .NET [project file](#), which lists the files and assemblies that comprise your application.
- **Dockerfile:** You can use the provided Dockerfile for testing, or replace it with your own. If you use your own, make sure to:
 - Set the FROM property to the [URI of the base image](#). The base image and the TargetFramework in the `MyFunction.csproj` file must both use the same .NET version. For example, to use .NET 9:
 - Dockerfile: FROM *public.ecr.aws/lambda/dotnet:9*
 - MyFunction.csproj: <TargetFramework>*net9.0*</TargetFramework>
 - Set the CMD argument to the Lambda function handler. This should match the image-command in `aws-lambda-tools-defaults.json`.

3. Install the Amazon.Lambda.Tools [.NET Global Tool](#).

```
dotnet tool install -g Amazon.Lambda.Tools
```

If Amazon.Lambda.Tools is already installed, make sure that you have the latest version.

```
dotnet tool update -g Amazon.Lambda.Tools
```

4. Change the directory to *MyFunction*/src/*MyFunction*, if you're not there already.

```
cd src/MyFunction
```

5. Use Amazon.Lambda.Tools to build the Docker image, push it to a new Amazon ECR repository, and deploy the Lambda function.

For `--function-role`, specify the role name—not the Amazon Resource Name (ARN)—of the [execution role](#) for the function. For example, `lambda-role`.

```
dotnet lambda deploy-function MyFunction --function-role lambda-role
```

For more information about the Amazon.Lambda.Tools .NET Global Tool, see the [AWS Extensions for .NET CLI](#) repository on GitHub.

6. Invoke the function.

```
dotnet lambda invoke-function MyFunction --payload "Testing the function"
```

If everything is successful, you see a response similar to the following:

```
Payload:
{"Lower":"testing the function","Upper":"TESTING THE FUNCTION"}

Log Tail:
INIT_REPORT Init Duration: 9999.81 ms   Phase: init       Status: timeout
START RequestId: 12378346-f302-419b-b1f2-deaa1e8423ed Version: $LATEST
END RequestId: 12378346-f302-419b-b1f2-deaa1e8423ed
REPORT RequestId: 12378346-f302-419b-b1f2-deaa1e8423ed   Duration: 3173.06 ms
      Billed Duration: 3174 ms           Memory Size: 512 MB       Max Memory Used: 24 MB
```

7. Delete the Lambda function.

```
dotnet lambda delete-function MyFunction
```

Using an alternative base image with the runtime interface client

If you use an [OS-only base image](#) or an alternative base image, you must include the runtime interface client in your image. The runtime interface client extends the [Runtime API](#), which manages the interaction between Lambda and your function code.

The following example demonstrates how to build a container image for .NET using a non-AWS base image, and how to add the [Amazon.Lambda.RuntimeSupport package](#), which is the Lambda runtime interface client for .NET. The example Dockerfile uses the Microsoft .NET 8 base image.

Prerequisites

To complete the steps in this section, you must have the following:

- [.NET SDK](#) – The following steps use a .NET 9 base image. Make sure that your .NET version matches the version of the base image that you specify in your Dockerfile.
- [Docker](#) (minimum version 25.0.0)
- The Docker [buildx plugin](#).

Creating and deploying an image using an alternative base image

1. Install the [Amazon.Lambda.Templates](#) NuGet package.

```
dotnet new install Amazon.Lambda.Templates
```

2. Create a .NET project using the `lambda.CustomRuntimeFunction` template. This template includes the [Amazon.Lambda.RuntimeSupport](#) package.

```
dotnet new lambda.CustomRuntimeFunction --name MyFunction --region us-east-1
```

3. Navigate to the *MyFunction*/src/*MyFunction* directory. This is where the project files are stored. Examine the following files:
 - **aws-lambda-tools-defaults.json** – This file is where you specify the command line options when deploying your Lambda function.
 - **Function.cs** – The code contains a class with a `Main` method that initializes the `Amazon.Lambda.RuntimeSupport` library as the bootstrap. The `Main` method is the entry point for the function's process. The `Main` method wraps the function handler in a wrapper that the bootstrap can work with. For more information, see [Using Amazon.Lambda.RuntimeSupport as a class library](#) in the GitHub repository.
 - **MyFunction.csproj** – A .NET [project file](#), which lists the files and assemblies that comprise your application.
 - **Readme.md** – This file contains more information about the sample Lambda function.

4. Open the `aws-lambda-tools-defaults.json` file and Add the following lines:

```
"package-type": "image",  
"docker-host-build-output-dir": "./bin/Release/lambda-publish"
```

- **package-type:** Defines the deployment package as a container image.
- **docker-host-build-output-dir:** Sets the output directory for the build process.

Example `aws-lambda-tools-defaults.json`

```
{  
  "Information": [  
    "This file provides default values for the deployment wizard inside Visual  
    Studio and the AWS Lambda commands added to the .NET Core CLI.",  
    "To learn more about the Lambda commands with the .NET Core CLI execute the  
    following command at the command line in the project root directory.",  
    "dotnet lambda help",  
    "All the command line options for the Lambda command can be specified in this  
    file."  
  ],  
  "profile": "",  
  "region": "us-east-1",  
  "configuration": "Release",  
  "function-runtime": "provided.al2023",  
  "function-memory-size": 256,  
  "function-timeout": 30,  
  "function-handler": "bootstrap",  
  "msbuild-parameters": "--self-contained true",  
  "package-type": "image",  
  "docker-host-build-output-dir": "./bin/Release/lambda-publish"  
}
```

5. Create a Dockerfile in the `MyFunction/src/MyFunction` directory. The following example Dockerfile uses a Microsoft .NET base image instead of an [AWS base image](#).
 - Set the FROM property to the base image identifier. The base image and the TargetFramework in the `MyFunction.csproj` file must both use the same .NET version.
 - Use the COPY command to copy the function into the `/var/task` directory.

- Set the ENTRYPOINT to the module that you want the Docker container to run when it starts. In this case, the module is the bootstrap, which initializes the `Amazon.Lambda.RuntimeSupport` library.

Note that the example Dockerfile does not include a [USER instruction](#). When you deploy a container image to Lambda, Lambda automatically defines a default Linux user with least-privileged permissions. This is different from standard Docker behavior which defaults to the root user when no USER instruction is provided.

Example Dockerfile

```
# You can also pull these images from DockerHub amazon/aws-lambda-dotnet:8
FROM mcr.microsoft.com/dotnet/runtime:9.0

# Set the image's internal work directory
WORKDIR /var/task

# Copy function code to Lambda-defined environment variable
COPY "bin/Release/net9.0/linux-x64" .

# Set the entrypoint to the bootstrap
ENTRYPOINT ["/usr/bin/dotnet", "exec", "/var/task/bootstrap.dll"]
```

6. Install the Amazon.Lambda.Tools [.NET Global Tools extension](#).

```
dotnet tool install -g Amazon.Lambda.Tools
```

If Amazon.Lambda.Tools is already installed, make sure that you have the latest version.

```
dotnet tool update -g Amazon.Lambda.Tools
```

7. Use Amazon.Lambda.Tools to build the Docker image, push it to a new Amazon ECR repository, and deploy the Lambda function.

For `--function-role`, specify the role name—not the Amazon Resource Name (ARN)—of the [execution role](#) for the function. For example, `lambda-role`.

```
dotnet lambda deploy-function MyFunction --function-role lambda-role
```

For more information about the Amazon.Lambda.Tools .NET CLI extension, see the [AWS Extensions for .NET CLI](#) repository on GitHub.

8. Invoke the function.

```
dotnet lambda invoke-function MyFunction --payload "Testing the function"
```

If everything is successful, you see the following:

Payload:

"TESTING THE FUNCTION"

Log Tail:

START RequestId: *id* Version: \$LATEST

END RequestId: *id*

REPORT RequestId: <i>id</i>	Duration: 0.99 ms	Billed Duration: 1 ms	Memory
Size: 256 MB	Max Memory Used: 12 MB		

9. Delete the Lambda function.

```
dotnet lambda delete-function MyFunction
```

Compile .NET Lambda function code to a native runtime format

.NET 8 supports native ahead-of-time (AOT) compilation. With native AOT, you can compile your Lambda function code to a native runtime format, which removes the need to compile .NET code at runtime. Native AOT compilation can reduce the cold start time for Lambda functions that you write in .NET. For more information, see [Introducing the .NET 8 runtime for AWS Lambda](#) on the AWS Compute Blog.

Sections

- [Lambda runtime](#)
- [Prerequisites](#)
- [Getting started](#)
- [Serialization](#)
- [Trimming](#)
- [Troubleshooting](#)

Lambda runtime

To deploy a Lambda function build with native AOT compilation, use the managed .NET 8 Lambda runtime. This runtime supports the use of both x86_64 and arm64 architectures.

When you deploy a .NET Lambda function without using AOT, your application is first compiled into Intermediate Language (IL) code. At runtime, the just-in-time (JIT) compiler in the Lambda runtime takes the IL code and compiles it into machine code as needed. With a Lambda function that is compiled ahead of time with native AOT, you compile your code into machine code when you deploy your function, so you're not dependent on the .NET runtime or SDK in the Lambda runtime to compile your code before it runs.

One limitation of AOT is that your application code must be compiled in an environment with the same Amazon Linux 2023 (AL2023) operating system that the .NET 8 runtime uses. The .NET Lambda CLI provides functionality to compile your application in a Docker container using an AL2023 image.

To avoid potential issues with cross-architecture compatibility, we strongly recommend that you compile your code in an environment with the same processor architecture that you configure for your function. To learn more about the limitations of cross-architecture compilation, see [Cross-compilation](#) in the Microsoft .NET documentation.

Prerequisites

Docker

To use native AOT, your function code must be compiled in an environment with the same AL2023 operating system as the .NET 8 runtime. The .NET CLI commands in the following sections use Docker to develop and build Lambda functions in an AL2023 environment.

.NET 8 SDK

Native AOT compilation is a feature of .NET 8. You must install the [.NET 8 SDK](#) on your build machine, not only the runtime.

Amazon.Lambda.Tools

To create your Lambda functions, you use the [Amazon.Lambda.Tools .NET Global Tools extension](#). To install Amazon.Lambda.Tools, run the following command:

```
dotnet tool install -g Amazon.Lambda.Tools
```

For more information about the Amazon.Lambda.Tools .NET CLI extension, see the [AWS Extensions for .NET CLI](#) repository on GitHub.

Amazon.Lambda.Templates

To generate your Lambda function code, use the [Amazon.Lambda.Templates](#) NuGet package. To install this template package, run the following command:

```
dotnet new install Amazon.Lambda.Templates
```

Getting started

Both the .NET Global CLI and the AWS Serverless Application Model (AWS SAM) provide getting started templates for building applications using native AOT. To build your first native AOT Lambda function, carry out the steps in the following instructions.

To initialize and deploy a native AOT compiled Lambda function

1. Initialize a new project using the native AOT template and then navigate into the directory containing the created .cs and .csproj files. In this example, we name our function NativeAotSample.

```
dotnet new lambda.NativeAOT -n NativeAotSample
cd ./NativeAotSample/src/NativeAotSample
```

The `Function.cs` file created by the native AOT template contains the following function code.

```
using Amazon.Lambda.Core;
using Amazon.Lambda.RuntimeSupport;
using Amazon.Lambda.Serialization.SystemTextJson;
using System.Text.Json.Serialization;

namespace NativeAotSample;

public class Function
{
    /// <summary>
    /// The main entry point for the Lambda function. The main function is called
    /// once during the Lambda init phase. It
    /// initializes the .NET Lambda runtime client passing in the function handler
    /// to invoke for each Lambda event and
    /// the JSON serializer to use for converting Lambda JSON format to the .NET
    /// types.
    /// </summary>
    private static async Task Main()
    {
        Func<string, ILambdaContext, string> handler = FunctionHandler;
        await LambdaBootstrapBuilder.Create(handler, new
        SourceGeneratorLambdaJsonSerializer<LambdaFunctionJsonSerializerContext>())
            .Build()
            .RunAsync();
    }

    /// <summary>
    /// A simple function that takes a string and does a ToUpper.
    ///
    /// To use this handler to respond to an AWS event, reference the appropriate
    /// package from
    /// https://github.com/aws/aws-lambda-dotnet#events
    /// and change the string input parameter to the desired event type. When the
    /// event type
    /// is changed, the handler type registered in the main method needs to be
    /// updated and the LambdaFunctionJsonSerializerContext
```

```

    /// defined below will need the JsonSerializer updated. If the return type
    and event type are different then the
    /// LambdaFunctionJsonSerializerContext must have two JsonSerializer
    attributes, one for each type.
    ///
    /// When using Native AOT extra testing with the deployed Lambda functions is
    required to ensure
    /// the libraries used in the Lambda function work correctly with Native AOT. If
    a runtime
    /// error occurs about missing types or methods the most likely solution will be
    to remove references to trim-unsafe
    /// code or configure trimming options. This sample defaults to partial TrimMode
    because currently the AWS
    /// SDK for .NET does not support trimming. This will result in a larger
    executable size, and still does not
    /// guarantee runtime trimming errors won't be hit.
    /// </summary>
    /// <param name="input"></param>
    /// <param name="context"></param>
    /// <returns></returns>
    public static string FunctionHandler(string input, ILambdaContext context)
    {
        return input.ToUpper();
    }
}

/// <summary>
/// This class is used to register the input event and return type for the
    FunctionHandler method with the System.Text.Json source generator.
/// There must be a JsonSerializer attribute for each type used as the input and
    return type or a runtime error will occur
/// from the JSON serializer unable to find the serialization information for
    unknown types.
/// </summary>
[JsonSerializable(typeof(string))]
public partial class LambdaFunctionJsonSerializerContext : JsonSerializerContext
{
    /// By using this partial class derived from JsonSerializerContext, we can
    generate reflection free JSON Serializer code at compile time
    /// which can deserialize our class and properties. However, we must attribute
    this class to tell it what types to generate serialization code for.
    /// See https://docs.microsoft.com/en-us/dotnet/standard/serialization/system-
    text-json-source-generation

```

Native AOT compiles your application into a single, native binary. The entrypoint of that binary is the static `Main` method. Within static `Main`, the Lambda runtime is bootstrapped and the `FunctionHandler` method set up. As part of the runtime bootstrap, a source generated serializer is configured using new `SourceGeneratorLambdaJsonSerializer<LambdaFunctionJsonSerializerContext>()`

2. To deploy your application to Lambda, ensure that Docker is running in your local environment and run the following command.

```
dotnet lambda deploy-function
```

Behind the scenes, the .NET global CLI downloads an AL2023 Docker image and compiles your application code inside a running container. The compiled binary is output back to your local filesystem before being deployed to Lambda.

3. Test your function by running the following command. Replace `<FUNCTION_NAME>` with the name you chose for your function in the deployment wizard.

```
dotnet lambda invoke-function <FUNCTION_NAME> --payload "hello world"
```

The response from the CLI includes performance details for the cold start (initialization duration) and total run time for your function invocation.

4. To delete the AWS resources you created by following the preceding steps, run the following command. Replace `<FUNCTION_NAME>` with the name you chose for your function in the deployment wizard. By deleting AWS resources that you're no longer using, you prevent unnecessary charges being billed to your AWS account.

```
dotnet lambda delete-function <FUNCTION_NAME>
```

Serialization

To deploy functions to Lambda using native AOT, your function code must use [source generated serialization](#). Instead of using run-time reflection to gather the metadata needed to access object properties for serialization, source generators generate C# source files that are compiled when you build your application. To configure your source generated serializer correctly, ensure that you include any input and output objects your function uses, as well as any custom types. For

example, a Lambda function that receives events from an API Gateway REST API and returns a custom Product type would include a serializer defined as follows.

```
[JsonSerializable(typeof(APIGatewayProxyRequest))]  
[JsonSerializable(typeof(APIGatewayProxyResponse))]  
[JsonSerializable(typeof(Product))]  
public partial class CustomSerializer : JsonSerializerContext  
{  
}
```

Trimming

Native AOT trims your application code as part of the compilation to ensure that the binary is as small as possible. .NET 8 for Lambda provides improved trimming support compared to previous versions of .NET. Support has been added to the [Lambda runtime libraries](#), [AWS .NET SDK](#), [.NET Lambda Annotations](#), and .NET 8 itself.

These improvements offer the potential to eliminate build-time trimming warnings, but .NET will never be completely trim safe. This means that parts of libraries that your function relies on may be trimmed out as part of the compilation step. You can manage this by defining `TrimmerRootAssemblies` as part of your `.csproj` file as shown in the following example.

```
<ItemGroup>  
  <TrimmerRootAssembly Include="AWSSDK.Core" />  
  <TrimmerRootAssembly Include="AWSXRayRecorder.Core" />  
  <TrimmerRootAssembly Include="AWSXRayRecorder.Handlers.AwsSdk" />  
  <TrimmerRootAssembly Include="Amazon.Lambda.APIGatewayEvents" />  
  <TrimmerRootAssembly Include="bootstrap" />  
  <TrimmerRootAssembly Include="Shared" />  
</ItemGroup>
```

Note that when you receive a trim warning, adding the class that generates the warning to `TrimmerRootAssembly` might not resolve the issue. A trim warning indicates that the class is trying to access some other class that can't be determined until runtime. To avoid runtime errors, add this second class to `TrimmerRootAssembly`.

To learn more about managing trim warnings, see [Introduction to trim warnings](#) in the Microsoft .NET documentation.

Troubleshooting

Error: Cross-OS native compilation is not supported.

Your version of the Amazon.Lambda.Tools .NET Core global tool is out of date. Update to the latest version and try again.

Docker: image operating system "linux" cannot be used on this platform.

Docker on your system is configured to use Windows containers. Swap to Linux containers to run the native AOT build environment.

For more information about common errors, see the [AWS NativeAOT for .NET](#) repository on GitHub.

Using the Lambda context object to retrieve C# function information

When Lambda runs your function, it passes a context object to the [handler](#). This object provides properties with information about the invocation, function, and execution environment.

Context properties

- `FunctionName` – The name of the Lambda function.
- `FunctionVersion` – The [version](#) of the function.
- `InvokedFunctionArn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `MemoryLimitInMB` – The amount of memory that's allocated for the function.
- `AwsRequestId` – The identifier of the invocation request.
- `LogGroupName` – The log group for the function.
- `LogStreamName` – The log stream for the function instance.
- `RemainingTime (TimeSpan)` – The number of milliseconds left before the execution times out.
- `Identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
- `ClientContext` – (mobile apps) Client context that's provided to Lambda by the client application.
- `Logger` The [logger object](#) for the function.

You can use information in the `ILambdaContext` object to output information about your function's invocation for monitoring purposes. The following code provides an example of how to add context information to a structured logging framework. In this example, the function adds `AwsRequestId` to the log outputs. The function also uses the `RemainingTime` property to cancel an inflight task if the Lambda function timeout is about to be reached.

```
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))

namespace GetProductHandler;

public class Function
```

```
{
    private readonly IDatabaseRepository _repo;

    public Function()
    {
        this._repo = new DatabaseRepository();
    }

    public async Task<APIGatewayProxyResponse> FunctionHandler(APIGatewayProxyRequest
request, ILambdaContext context)
    {
        Logger.AppendKey("AwsRequestId", context.AwsRequestId);

        var id = request.PathParameters["id"];

        using var cts = new CancellationTokensource();

        try
        {
            cts.CancelAfter(context.RemainingTime.Add(TimeSpan.FromSeconds(-1)));

            var databaseRecord = await this._repo.GetById(id, cts.Token);

            return new APIGatewayProxyResponse
            {
                StatusCode = (int)HttpStatusCode.OK,
                Body = JsonSerializer.Serialize(databaseRecord)
            };
        }
        catch (Exception ex)
        {
            return new APIGatewayProxyResponse
            {
                StatusCode = (int)HttpStatusCode.InternalServerError,
                Body = JsonSerializer.Serialize(new { error = ex.Message })
            };
        }
        finally
        {
            cts.Cancel();
        }
    }
}
```

Log and monitor C# Lambda functions

AWS Lambda automatically monitors Lambda functions and sends log entries to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation and other output from your function's code to the log stream. For more information about CloudWatch Logs, see [Sending Lambda function logs to CloudWatch Logs](#).

Sections

- [Creating a function that returns logs](#)
- [Using Lambda advanced logging controls with .NET](#)
- [Additional logging tools and libraries](#)
- [Using Powertools for AWS Lambda \(.NET\) and AWS SAM for structured logging](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)
- [Viewing logs using the AWS Command Line Interface \(AWS CLI\)](#)
- [Deleting logs](#)

Creating a function that returns logs

To output logs from your function code, you can use the [ILambdaLogger](#) on the context object, the methods on the [Console class](#), or any logging library that writes to stdout or stderr.

The .NET runtime logs the START, END, and REPORT lines for each invocation. The report line provides the following details.

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.
- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.

- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

Using Lambda advanced logging controls with .NET

To give you more control over how your functions' logs are captured, processed, and consumed, you can configure the following logging options for supported .NET runtimes:

- **Log format** - select between plain text and structured JSON format for your function's logs
- **Log level** - for logs in JSON format, choose the detail level of the logs Lambda sends to CloudWatch, such as ERROR, DEBUG, or INFO
- **Log group** - choose the CloudWatch log group your function sends logs to

For more information about these logging options, and instructions on how to configure your function to use them, see [the section called “Configuring advanced logging controls for Lambda functions”](#).

To use the log format and log level options with your .NET Lambda functions, see the guidance in the following sections.

Using structured JSON log format with .NET

If you select JSON for your function's log format, Lambda will send logs output using [ILambdaLogger](#) as structured JSON. Each JSON log object contains at least five key value pairs with the following keys:

- "timestamp" - the time the log message was generated
- "level" - the log level assigned to the message
- "requestId" - the unique request ID for the function invocation
- "traceId" - the `_X_AMZN_TRACE_ID` environment variable
- "message" - the contents of the log message

The `ILambdaLogger` instance can add additional key value pairs, for example when logging exceptions. You can also supply your own additional parameters as described in the section [the section called “Customer-provided log parameters”](#).

Note

If your code already uses another logging library to produce JSON-formatted logs, ensure that your function's log format is set to plain text. Setting the log format to JSON will result in your log outputs being double-encoded.

The following example logging command shows how to write a log message with the level `INFO`.

Example.NET logging code

```
context.Logger.LogInformation("Fetching cart from database");
```

You can also use a generic log method that takes the log level as an argument as shown in the following example.

```
context.Logger.Log(LogLevel.Information, "Fetching cart from database");
```

The log output by these example code snippets would be captured in CloudWatch Logs as follows:

Example JSON log record

```
{
  "timestamp": "2025-09-07T01:30:06.977Z",
  "level": "Information",
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",
  "message": "Fetching cart from database"
}
```

Note

If you configure your function's log format to use plain text rather than JSON, then the log level captured in the message follows the Microsoft convention of using a four-character label. For example, a log level of `Debug` is represented in the message as `debug`.

When you configure your function to use JSON formatted logs, the log level captured in the log uses the full label as shown in the example JSON log record.

If you don't assign a level to your log output, Lambda will automatically assign it the level INFO.

Logging exceptions in JSON

When using structured JSON logging with `ILambdaLogger`, you can log exceptions in your code as shown in the following example.

Example usage of exception logging

```
try
{
    connection.ExecuteQuery(query);
}
catch(Exception e)
{
    context.Logger.LogWarning(e, "Error executing query");
}
```

The log format output by this code is shown in the following example JSON. Note that the message property in the JSON is populated using the message argument provided in the `LogWarning` call, while the `errorMessage` property comes from the Message property of the exception itself.

Example JSON log record

```
{
  "timestamp": "2025-09-07T01:30:06.977Z",
  "level": "Warning",
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",
  "message": "Error executing query",
  "errorType": "System.Data.SqlClient.SqlException",
  "errorMessage": "Connection closed",
  "stackTrace": ["<call exception.StackTrace>"]
}
```

If your function's logging format is set to JSON, Lambda also outputs JSON-formatted log messages when your code throws an uncaught exception. The following example code snippet and log message show how uncaught exceptions are logged.

Example exception code

```
throw new ApplicationException("Invalid data");
```

Example JSON log record

```
{
  "timestamp": "2025-09-07T01:30:06.977Z",
  "level": "Error",
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",
  "message": "Invalid data",
  "errorType": "System.ApplicationException",
  "errorMessage": "Invalid data",
  "stackTrace": ["<call exception.StackTrace>"]
}
```

Customer-provided log parameters

With JSON-formatted log messages, you can supply additional log parameters and include these in the log message. The following code snippet example shows a command to add two user-supplied parameters labeled `retryAttempt` and `uri`. In the example, the value of these parameters come from the `retryAttempt` and `uriDestination` arguments passed into the logging command.

Example JSON logging command with additional parameters

```
context.Logger.LogInformation("Starting retry {retryAttempt} to make GET request to {uri}", retryAttempt, uriDestination);
```

The log message output by this command is shown in the following example JSON.

Example JSON log record

```
{
  "timestamp": "2025-09-07T01:30:06.977Z",
  "level": "Information",
```

```
"requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",  
"traceId": "1-6408af34-50f56f5b5677a7d763973804",  
"message": "Starting retry 1 to make GET request to http://example.com/",  
"retryAttempt": 1,  
"uri": "http://example.com/"  
}
```

Tip

You can also use positional properties instead of names when specifying additional parameters. For example, the logging command in the previous example could also be written as follows:

```
context.Logger.LogInformation("Starting retry {0} to make GET request to {1}",  
    retryAttempt, uriDestination);
```

Note that when you supply additional logging parameters, Lambda captures them as top-level properties in the JSON log record. This approach differs from some popular .NET logging libraries such as Serilog, which captures additional parameters in a separate child object.

If the argument you supply for an additional parameter is a complex object, by default Lambda uses the `ToString()` method to supply the value. To indicate that an argument should be JSON serialized, use the `@` prefix as shown in the following code snippet. In this example, `User` is an object with `FirstName` and `LastName` properties.

Example JSON logging command with JSON serialized object

```
context.Logger.LogInformation("User {@user} logged in", User);
```

The log message output by this command is shown in the following example JSON.

Example JSON log record

```
{  
  "timestamp": "2025-09-07T01:30:06.977Z",  
  "level": "Information",  
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",  
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",  
  "message": "User {@user} logged in",  
}
```

```
"user":  
{  
  "FirstName": "John",  
  "LastName": "Doe"  
}  
}
```

If the argument for an additional parameter is an array or implements `ICollection` or `IDictionary`, then Lambda adds the argument to the JSON log message as an array as shown in the following example JSON log record. In this example, `{users}` takes an `ICollection` argument containing instances of the `User` property with the same format as the previous example. Lambda converts this `ICollection` into an array, with each value being created using the `ToString` method.

Example JSON log record with an `ICollection` argument

```
{  
  "timestamp": "2025-09-07T01:30:06.977Z",  
  "level": "Information",  
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",  
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",  
  "message": "{users} have joined the group",  
  "users":  
  [  
    "Rosalez, Alejandro",  
    "Stiles, John"  
  ]  
}
```

You can also JSON serialize the list by using the `@` prefix in your logging command. In the following example JSON log record, the `users` property is JSON serialized.

Example JSON log record with a JSON serialized `ICollection` argument

```
{  
  "timestamp": "2025-09-07T01:30:06.977Z",  
  "level": "Information",  
  "requestId": "8f711428-7e55-46f9-ae88-2a65d4f85fc5",  
  "traceId": "1-6408af34-50f56f5b5677a7d763973804",  
  "message": "{@users} have joined the group",  
  "users":  
  [  
    {  
      "FirstName": "John",  
      "LastName": "Doe"  
    }  
  ]  
}
```

```
        "FirstName": "Alejandro",
        "LastName": "Rosalez"
    },
    {
        "FirstName": "John",
        "LastName": "Stiles"
    }
]
```

Using log-level filtering with .NET

By configuring log-level filtering, you can choose to send only logs of a certain detail level or lower to CloudWatch Logs. To learn how to configure log-level filtering for your function, see [the section called “Log-level filtering”](#).

For AWS Lambda to filter your log messages by log level, you can either use JSON formatted logs or use the .NET Console methods to output log messages. To create JSON formatted logs, [configure your function's log type to JSON](#) and use the `ILambdaLogger` instance.

With JSON-formatted logs, Lambda filters your log outputs using the “level” key value pair in the JSON object described in [the section called “Using structured JSON log format with .NET”](#).

If you use the .NET Console methods to write messages to CloudWatch Logs, Lambda applies log levels to your messages as follows:

- **Console.WriteLine method** - Lambda applies a log-level of INFO
- **Console.Error method** - Lambda applies a log-level of ERROR

When you configure your function to use log-level filtering, you must select from the following options for the level of logs you want Lambda to send to CloudWatch Logs. Note the mapping of the log levels used by Lambda with the standard Microsoft levels used by the .NET `ILambdaLogger`.

Lambda log level	Equivalent Microsoft level	Standard usage
TRACE (most detail)	Trace	The most fine-grained information used to trace the path of your code's execution

Lambda log level	Equivalent Microsoft level	Standard usage
DEBUG	Debug	Detailed information for system debugging
INFO	Information	Messages that record the normal operation of your function
WARN	Warning	Messages about potential errors that may lead to unexpected behavior if unaddressed
ERROR	Error	Messages about problems that prevent the code from performing as expected
FATAL (least detail)	Critical	Messages about serious errors that cause the application to stop functioning

Lambda sends logs of the selected detail level and lower to CloudWatch. For example, if you configure a log level of WARN, Lambda will send logs corresponding to the WARN, ERROR, and FATAL levels.

Additional logging tools and libraries

[Powertools for AWS Lambda \(.NET\)](#) is a developer toolkit to implement Serverless best practices and increase developer velocity. The [Logging utility](#) provides a Lambda optimized logger which includes additional information about function context across all your functions with output structured as JSON. Use this utility to do the following:

- Capture key fields from the Lambda context, cold start and structures logging output as JSON
- Log Lambda invocation events when instructed (disabled by default)
- Print all the logs only for a percentage of invocations via log sampling (disabled by default)
- Append additional keys to structured log at any point in time

- Use a custom log formatter (Bring Your Own Formatter) to output logs in a structure compatible with your organization's Logging RFC

Using Powertools for AWS Lambda (.NET) and AWS SAM for structured logging

Follow the steps below to download, build, and deploy a sample Hello World C# application with integrated [Powertools for AWS Lambda \(.NET\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a `hello world` message.

Prerequisites

To complete the steps in this section, you must have the following:

- .NET 8
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World TypeScript template.

```
sam init --app-template hello-world-powertools-dotnet --name sam-app --package-type Zip --runtime dotnet6 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

- Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

 **Note**

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

- Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query
'Stacks[0].Outputs[?OutputKey=='HelloWorldApi'].OutputValue' --output text
```

- Invoke the API endpoint:

```
curl -X GET <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

- To get the logs for the function, run [sam logs](#). For more information, see [Working with logs](#) in the *AWS Serverless Application Model Developer Guide*.

```
sam logs --stack-name sam-app
```

The log output looks like this:

```

```

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

Managing log retention

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or configure a retention period after which CloudWatch automatically deletes the logs. To set up log retention, add the following to your AWS SAM template:

```

Resources:
  HelloWorldFunction:
    Type: AWS::Serverless::Function
    Properties:
      # Omitting other properties

  LogGroup:

```

```
Type: AWS::Logs::LogGroup
Properties:
  LogGroupName: !Sub "/aws/lambda/${HelloWorldFunction}"
  RetentionInDays: 7
```

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (**/aws/lambda/*your-function-name***).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElk0iA4N2QwNDRI0C1mMTU0LTExZTgt0GNkYS0yOTc0YzVlNGZiMjEgVmVyc2lvb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ22luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0\"",ask/lib:/opt/lib",
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8   Duration: 79.67 ms           Billed
Duration: 80 ms           Memory Size: 128 MB           Max Memory Used: 73 MB
```

The `base64` utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"/'/g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
```

```

}
{
  "events": [
    {

```

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Instrumenting C# code in AWS Lambda

Lambda integrates with AWS X-Ray to help you trace, debug, and optimize Lambda applications. You can use X-Ray to trace a request as it traverses resources in your application, which may include Lambda functions and other AWS services.

To send tracing data to X-Ray, you can use one of three SDK libraries:

- [AWS Distro for OpenTelemetry \(ADOT\)](#) – A secure, production-ready, AWS-supported distribution of the OpenTelemetry (OTel) SDK.
- [AWS X-Ray SDK for .NET](#) – An SDK for generating and sending trace data to X-Ray.
- [Powertools for AWS Lambda \(.NET\)](#) – A developer toolkit to implement Serverless best practices and increase developer velocity.

Each of the SDKs offer ways to send your telemetry data to the X-Ray service. You can then use X-Ray to view, filter, and gain insights into your application's performance metrics to identify issues and opportunities for optimization.

Important

The X-Ray and Powertools for AWS Lambda SDKs are part of a tightly integrated instrumentation solution offered by AWS. The ADOT Lambda Layers are part of an industry-wide standard for tracing instrumentation that collect more data in general, but may not be suited for all use cases. You can implement end-to-end tracing in X-Ray using either solution. To learn more about choosing between them, see [Choosing between the AWS Distro for Open Telemetry and X-Ray SDKs](#).

Sections

- [Using Powertools for AWS Lambda \(.NET\) and AWS SAM for tracing](#)
- [Using the X-Ray SDK to instrument your .NET functions](#)
- [Activating tracing with the Lambda console](#)
- [Activating tracing with the Lambda API](#)
- [Activating tracing with CloudFormation](#)
- [Interpreting an X-Ray trace](#)

Using Powertools for AWS Lambda (.NET) and AWS SAM for tracing

Follow the steps below to download, build, and deploy a sample Hello World C# application with integrated [Powertools for AWS Lambda \(.NET\)](#) modules using the AWS SAM. This application implements a basic API backend and uses Powertools for emitting logs, metrics, and traces. It consists of an Amazon API Gateway endpoint and a Lambda function. When you send a GET request to the API Gateway endpoint, the Lambda function invokes, sends logs and metrics using Embedded Metric Format to CloudWatch, and sends traces to AWS X-Ray. The function returns a hello world message.

Prerequisites

To complete the steps in this section, you must have the following:

- .NET 8
- [AWS CLI version 2](#)
- [AWS SAM CLI version 1.75 or later](#). If you have an older version of the AWS SAM CLI, see [Upgrading the AWS SAM CLI](#).

Deploy a sample AWS SAM application

1. Initialize the application using the Hello World TypeScript template.

```
sam init --app-template hello-world-powertools-dotnet --name sam-app --package-type Zip --runtime dotnet6 --no-tracing
```

2. Build the app.

```
cd sam-app && sam build
```

3. Deploy the app.

```
sam deploy --guided
```

4. Follow the on-screen prompts. To accept the default options provided in the interactive experience, press Enter.

Note

For **HelloWorldFunction** may not have authorization defined, Is this okay?, make sure to enter y.

5. Get the URL of the deployed application:

```
aws cloudformation describe-stacks --stack-name sam-app --query  
'Stacks[0].Outputs[?OutputKey==`HelloWorldApi`].OutputValue' --output text
```

6. Invoke the API endpoint:

```
curl <URL_FROM_PREVIOUS_STEP>
```

If successful, you'll see this response:

```
{"message":"hello world"}
```

7. To get the traces for the function, run [sam traces](#).

```
sam traces
```

The trace output looks like this:

```
New XRay Service Graph  
Start time: 2023-02-20 23:05:16+08:00

8. This is a public API endpoint that is accessible over the internet. We recommend that you delete the endpoint after testing.

```
sam delete
```

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

Using the X-Ray SDK to instrument your .NET functions

You can instrument your function code to record metadata and trace downstream calls. To record detail about calls that your function makes to other resources and services, use the AWS X-Ray SDK for .NET. To get the SDK, add the `AWSXRayRecorder` packages to your project file.

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>

```

There are a range of Nuget packages that provide auto-instrumentation for AWS SDKs, Entity Framework and HTTP requests. To see the complete set of configuration options refer to [AWS X-Ray SDK for .NET](#) in the *AWS X-Ray Developer Guide*.

Once you have added the desired Nuget packages, configure auto-instrumentation. Best practice is to perform this configuration outside of your function's handler function. This allows you to take advantage of execution environment re-use to improve the performance of your function. In the following code example, the `RegisterXRayForAllServices` method is called in the function constructor to add instrumentation for all AWS SDK calls.

```
[assembly:
  LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))

namespace GetProductHandler;

public class Function
{
    private readonly IDatabaseRepository _repo;
```

```
public Function()
{
    // Add auto instrumentation for all AWS SDK calls
    // It is important to call this method before initializing any SDK clients
    AWSSDKHandler.RegisterXRayForAllServices();
    this._repo = new DatabaseRepository();
}

public async Task<APIGatewayProxyResponse> FunctionHandler(APIGatewayProxyRequest
request)
{
    var id = request.PathParameters["id"];

    var databaseRecord = await this._repo.GetById(id);

    return new APIGatewayProxyResponse
    {
        StatusCode = (int)HttpStatusCode.OK,
        Body = JsonSerializer.Serialize(databaseRecord)
    };
}
```

Activating tracing with the Lambda console

To toggle active tracing on your Lambda function with the console, follow these steps:

To turn on active tracing

1. Open the [Functions page](#) of the Lambda console.
2. Choose a function.
3. Choose **Configuration** and then choose **Monitoring and operations tools**.
4. Under **Additional monitoring tools**, choose **Edit**.
5. Under **CloudWatch Application Signals and AWS X-Ray**, choose **Enable** for **Lambda service traces**.
6. Choose **Save**.

Activating tracing with the Lambda API

Configure tracing on your Lambda function with the AWS CLI or AWS SDK, use the following API operations:

- [UpdateFunctionConfiguration](#)
- [GetFunctionConfiguration](#)
- [CreateFunction](#)

The following example AWS CLI command enables active tracing on a function named **my-function**.

```
aws lambda update-function-configuration --function-name my-function \
--tracing-config Mode=Active
```

Tracing mode is part of the version-specific configuration when you publish a version of your function. You can't change the tracing mode on a published version.

Activating tracing with CloudFormation

To activate tracing on an `AWS::Lambda::Function` resource in a CloudFormation template, use the `TracingConfig` property.

Example [function-inline.yml](#) – Tracing configuration

```
Resources:
  function:
    Type: AWS::Lambda::Function
    Properties:
      TracingConfig:
        Mode: Active
      ...
```

For an AWS Serverless Application Model (AWS SAM) `AWS::Serverless::Function` resource, use the `Tracing` property.

Example [template.yml](#) – Tracing configuration

```
Resources:
  function:
```

Type: [AWS::Serverless::Function](#)

Properties:

Tracing: Active

...

Interpreting an X-Ray trace

Your function needs permission to upload trace data to X-Ray. When you activate tracing in the Lambda console, Lambda adds the required permissions to your function's [execution role](#). Otherwise, add the [AWSXRayDaemonWriteAccess](#) policy to the execution role.

After you've configured active tracing, you can observe specific requests through your application. The [X-Ray service graph](#) shows information about your application and all its components. The following example shows an application with two functions. The primary function processes events and sometimes returns errors. The second function at the top processes errors that appear in the first's log group and uses the AWS SDK to call X-Ray, Amazon Simple Storage Service (Amazon S3), and Amazon CloudWatch Logs.

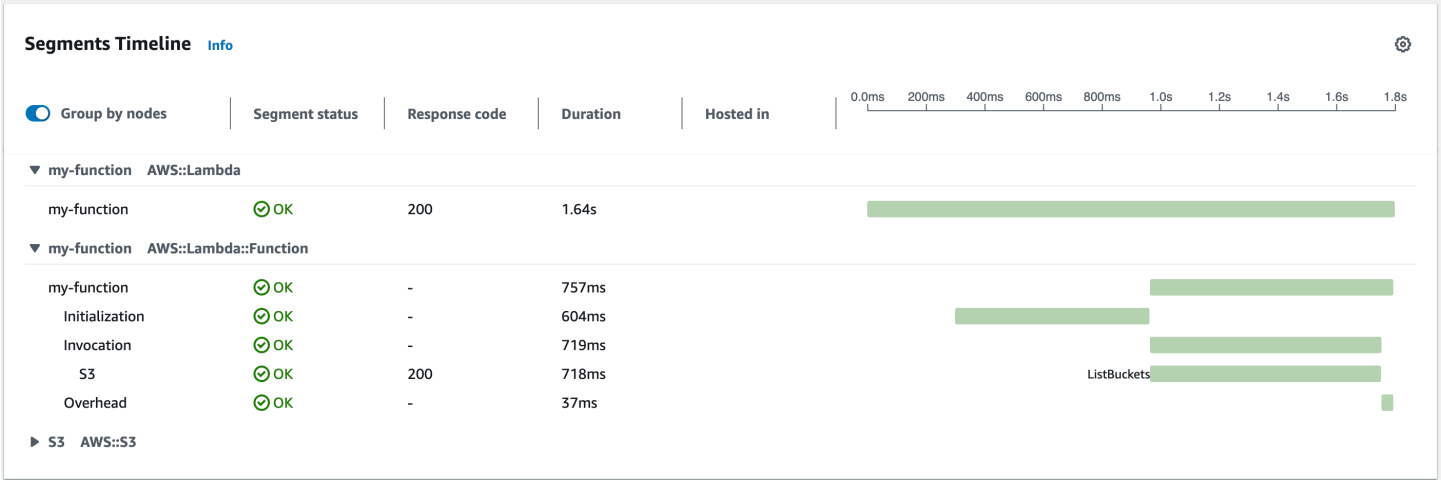

X-Ray doesn't trace all requests to your application. X-Ray applies a sampling algorithm to ensure that tracing is efficient, while still providing a representative sample of all requests. The sampling rate is 1 request per second and 5 percent of additional requests. You can't configure the X-Ray sampling rate for your functions.

In X-Ray, a *trace* records information about a request that is processed by one or more *services*. Lambda records 2 segments per trace, which creates two nodes on the service graph. The following image highlights these two nodes:

The first node on the left represents the Lambda service, which receives the invocation request. The second node represents your specific Lambda function. The following example shows a trace with these two segments. Both are named **my-function**, but one has an origin of `AWS::Lambda` and the other has an origin of `AWS::Lambda::Function`. If the `AWS::Lambda` segment shows an error, the Lambda service had an issue. If the `AWS::Lambda::Function` segment shows an error, your function had an issue.

This example expands the `AWS::Lambda::Function` segment to show its three subsegments.

 **Note**

AWS is currently implementing changes to the Lambda service. Due to these changes, you may see minor differences between the structure and content of system log messages and trace segments emitted by different Lambda functions in your AWS account.

The example trace shown here illustrates the old-style function segment. The differences between the old- and new-style segments are described in the following paragraphs.

These changes will be implemented during the coming weeks, and all functions in all AWS Regions except the China and GovCloud regions will transition to use the new-format log messages and trace segments.

The old-style function segment contains the following subsegments:

- **Initialization** – Represents time spent loading your function and running [initialization code](#). This subsegment only appears for the first event that each instance of your function processes.
- **Invocation** – Represents the time spent running your handler code.
- **Overhead** – Represents the time the Lambda runtime spends preparing to handle the next event.

The new-style function segment doesn't contain an Invocation subsegment. Instead, customer subsegments are attached directly to the function segment. For more information about the structure of the old- and new-style function segments, see [the section called “Understanding X-Ray traces”](#).

You can also instrument HTTP clients, record SQL queries, and create custom subsegments with annotations and metadata. For more information, see the [AWS X-Ray SDK for .NET](#) in the *AWS X-Ray Developer Guide*.

Pricing

You can use X-Ray tracing for free each month up to a certain limit as part of the AWS Free Tier. Beyond that threshold, X-Ray charges for trace storage and retrieval. For more information, see [AWS X-Ray pricing](#).

AWS Lambda function testing in C#

Note

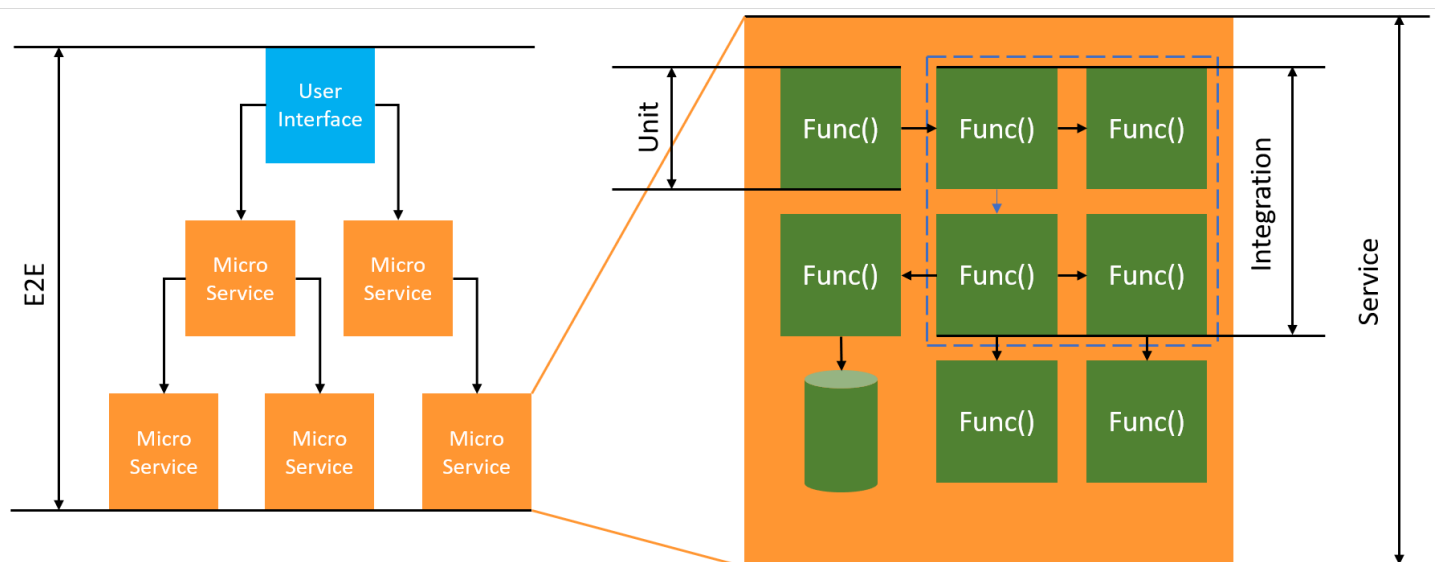

See the [Testing functions](#) chapter for a complete introduction to techniques and best practices for testing serverless solutions.

Testing serverless functions uses traditional test types and techniques, but you must also consider testing serverless applications as a whole. Cloud-based tests will provide the **most accurate** measure of quality of both your functions and serverless applications.

A serverless application architecture includes managed services that provide critical application functionality through API calls. For this reason, your development cycle should include automated tests that verify functionality when your function and services interact.

If you do not create cloud-based tests, you could encounter issues due to differences between your local environment and the deployed environment. Your continuous integration process should run tests against a suite of resources provisioned in the cloud before promoting your code to the next deployment environment, such as QA, Staging, or Production.

Continue reading this short guide to learn about testing strategies for serverless applications, or visit the [Serverless Test Samples repository](#) to dive in with practical examples, specific to your chosen language and runtime.

For serverless testing, you will still write *unit*, *integration* and *end-to-end* tests.

- **Unit tests** - Tests that run against an isolated block of code. For example, verifying the business logic to calculate the delivery charge given a particular item and destination.
- **Integration tests** - Tests involving two or more components or services that interact, typically in a cloud environment. For example, verifying a function processes events from a queue.
- **End-to-end tests** - Tests that verify behavior across an entire application. For example, ensuring infrastructure is set up correctly and that events flow between services as expected to record a customer's order.

Testing your serverless applications

You will generally use a mix of approaches to test your serverless application code, including testing in the cloud, testing with mocks, and occasionally testing with emulators.

Testing in the cloud

Testing in the cloud is valuable for all phases of testing, including unit tests, integration tests, and end-to-end tests. You run tests against code deployed in the cloud and interacting with cloud-based services. This approach provides the **most accurate** measure of quality of your code.

A convenient way to debug your Lambda function in the cloud is through the console with a test event. A *test event* is a JSON input to your function. If your function does not require input, the event can be an empty JSON document (`{}`). The console provides sample events for a variety of service integrations. After creating an event in the console, you can share it with your team to make testing easier and consistent.

Note

[Testing a function in the console](#) is a quick way to get started, but automating your test cycles ensures application quality and development speed.

Testing tools

To accelerate your development cycle, there are a number of tools and techniques you can use when testing your functions. For example, [AWS SAM Accelerate](#) and [AWS CDK watch mode](#) both decrease the time required to update cloud environments.

The way you define your Lambda function code makes it simple to add unit tests. Lambda requires a public, parameterless constructor to initialize your class. Introducing a second, internal constructor gives you control of the dependencies your application uses.

```
[assembly:
    LambdaSerializer(typeof(Amazon.Lambda.Serialization.SystemTextJson.DefaultLambdaJsonSerializer))

namespace GetProductHandler;

public class Function
{
    private readonly IDatabaseRepository _repo;

    public Function(): this(null)
    {
    }

    internal Function(IDatabaseRepository repo)
    {
        this._repo = repo ?? new DatabaseRepository();
    }

    public async Task<APIGatewayProxyResponse> FunctionHandler(APIGatewayProxyRequest
request)
    {
        var id = request.PathParameters["id"];

        var databaseRecord = await this._repo.GetById(id);

        return new APIGatewayProxyResponse
        {
            StatusCode = (int)HttpStatusCode.OK,
            Body = JsonSerializer.Serialize(databaseRecord)
        };
    }
}
```

To write a test for this function, you can initialize a new instance of your `Function` class and pass in a mocked implementation of the `IDatabaseRepository`. The below examples uses `XUnit`, `Moq`, and `FluentAssertions` to write a simple test ensuring the `FunctionHandler` returns a 200 status code.

```
using Xunit;
using Moq;
using FluentAssertions;

public class FunctionTests
{
    [Fact]
    public async Task TestLambdaHandler_WhenInputIsValid_ShouldReturn200StatusCode()
    {
        // Arrange
        var mockDatabaseRepository = new Mock<IDatabaseRepository>();

        var functionUnderTest = new Function(mockDatabaseRepository.Object);

        // Act
        var response = await functionUnderTest.FunctionHandler(new
        APIGatewayProxyRequest());

        // Assert
        response.StatusCode.Should().Be(200);
    }
}
```

For more detailed examples, including examples of asynchronous tests, see the [.NET testing samples repository](#) on GitHub.

Building Lambda functions with PowerShell

The following sections explain how common programming patterns and core concepts apply when you author Lambda function code in PowerShell.

Lambda provides the following sample applications for PowerShell:

- [blank-powershell](#) – A PowerShell function that shows the use of logging, environment variables, and the AWS SDK.

Before you get started, you must first set up a PowerShell development environment. For instructions on how to do this, see [Setting Up a PowerShell Development Environment](#).

To learn about how to use the AWSLambdaPSCore module to download sample PowerShell projects from templates, create PowerShell deployment packages, and deploy PowerShell functions to the AWS Cloud, see [Deploy PowerShell Lambda functions with .zip file archives](#).

Lambda provides the following runtimes for .NET languages:

Name	Identifier	Operating system	Deprecation date	Block function create	Block function update
.NET 10	dotnet10	Amazon Linux 2023	Nov 14, 2028	Dec 14, 2028	Jan 15, 2029
.NET 9 (container only)	dotnet9	Amazon Linux 2023	Nov 10, 2026	Not scheduled	Not scheduled
.NET 8	dotnet8	Amazon Linux 2023	Nov 10, 2026	Dec 10, 2026	Jan 11, 2027

Topics

- [Setting Up a PowerShell Development Environment](#)
- [Deploy PowerShell Lambda functions with .zip file archives](#)

- [Define Lambda function handler in PowerShell](#)
- [Using the Lambda context object to retrieve PowerShell function information](#)
- [Log and monitor Powershell Lambda functions](#)

Setting Up a PowerShell Development Environment

Lambda provides a set of tools and libraries for the PowerShell runtime. For installation instructions, see [Lambda tools for PowerShell](#) on GitHub.

The AWSLambdaPSCore module includes the following cmdlets to help author and publish PowerShell Lambda functions:

- **Get-AWSPowerShellLambdaTemplate** – Returns a list of getting started templates.
- **New-AWSPowerShellLambda** – Creates an initial PowerShell script based on a template.
- **Publish-AWSPowerShellLambda** – Publishes a given PowerShell script to Lambda.
- **New-AWSPowerShellLambdaPackage** – Creates a Lambda deployment package that you can use in a CI/CD system for deployment.

Deploy PowerShell Lambda functions with .zip file archives

A deployment package for the PowerShell runtime contains your PowerShell script, PowerShell modules that are required for your PowerShell script, and the assemblies needed to host PowerShell Core.

Creating the Lambda function

To get started writing and invoking a PowerShell script with Lambda, you can use the `New-AWSPowerShell11Lambda` cmdlet to create a starter script based on a template. You can use the `Publish-AWSPowerShell11Lambda` cmdlet to deploy your script to Lambda. Then you can test your script either through the command line or the Lambda console.

To create a new PowerShell script, upload it, and test it, do the following:

1. To view the list of available templates, run the following command:

```
PS C:\> Get-AWSPowerShell11LambdaTemplate

Template          Description
-----
Basic             Bare bones script
CodeCommitTrigger Script to process AWS CodeCommit Triggers
...
```

2. To create a sample script based on the Basic template, run the following command:

```
New-AWSPowerShell11Lambda -ScriptName MyFirstPSScript -Template Basic
```

A new file named `MyFirstPSScript.ps1` is created in a new subdirectory of the current directory. The name of the directory is based on the `-ScriptName` parameter. You can use the `-Directory` parameter to choose an alternative directory.

You can see that the new file has the following contents:

```
# PowerShell script file to run as a Lambda function
#
# When executing in Lambda the following variables are predefined.
# $LambdaInput - A PSObject that contains the Lambda function input data.
# $LambdaContext - An Amazon.Lambda.Core.ILambdaContext object that contains
information about the currently running Lambda environment.
```

```
#
# The last item in the PowerShell pipeline is returned as the result of the Lambda
# function.
#
# To include PowerShell modules with your Lambda function, like the
# AWSPowerShell.NetCore module, add a "#Requires" statement
# indicating the module and version.

#Requires -Modules @{ModuleName='AWSPowerShell.NetCore';ModuleVersion='3.3.618.0'}

# Uncomment to send the input to CloudWatch Logs
# Write-Host (ConvertTo-Json -InputObject $LambdaInput -Compress -Depth 5)
```

3. To see how log messages from your PowerShell script are sent to Amazon CloudWatch Logs, uncomment the `Write-Host` line of the sample script.

To demonstrate how you can return data back from your Lambda functions, add a new line at the end of the script with `$PSVersionTable`. This adds the `$PSVersionTable` to the PowerShell pipeline. After the PowerShell script is complete, the last object in the PowerShell pipeline is the return data for the Lambda function. `$PSVersionTable` is a PowerShell global variable that also provides information about the running environment.

After making these changes, the last two lines of the sample script look like this:

```
Write-Host (ConvertTo-Json -InputObject $LambdaInput -Compress -Depth 5)
$PSVersionTable
```

4. After editing the `MyFirstPSScript.ps1` file, change the directory to the script's location. Then run the following command to publish the script to Lambda:

```
Publish-AWSPowerShellLambda -ScriptPath .\MyFirstPSScript.ps1 -Name
MyFirstPSScript -Region us-east-2
```

Note that the `-Name` parameter specifies the Lambda function name, which appears in the Lambda console. You can use this function to invoke your script manually.

5. Invoke your function using the AWS Command Line Interface (AWS CLI) `invoke` command.

```
> aws lambda invoke --function-name MyFirstPSScript out
```

Define Lambda function handler in PowerShell

When a Lambda function is invoked, the Lambda handler invokes the PowerShell script.

When the PowerShell script is invoked, the following variables are predefined:

- ***\$LambdaInput*** – A PSObject that contains the input to the handler. This input can be event data (published by an event source) or custom input that you provide, such as a string or any custom data object.
- ***\$LambdaContext*** – An Amazon.Lambda.Core.ILambdaContext object that you can use to access information about the current invocation—such as the name of the current function, the memory limit, execution time remaining, and logging.

For example, consider the following PowerShell example code.

```
#Requires -Modules @{ModuleName='AWSPowerShell.NetCore';ModuleVersion='3.3.618.0'}  
Write-Host 'Function Name:' $LambdaContext.FunctionName
```

This script returns the `FunctionName` property that's obtained from the `$LambdaContext` variable.

Note

You're required to use the `#Requires` statement within your PowerShell scripts to indicate the modules that your scripts depend on. This statement performs two important tasks. 1) It communicates to other developers which modules the script uses, and 2) it identifies the dependent modules that AWS PowerShell tools need to package with the script, as part of the deployment. For more information about the `#Requires` statement in PowerShell, see [About requires](#). For more information about PowerShell deployment packages, see [Deploy PowerShell Lambda functions with .zip file archives](#).

When your PowerShell Lambda function uses the AWS PowerShell cmdlets, be sure to set a `#Requires` statement that references the `AWSPowerShell.NetCore` module, which supports PowerShell Core—and not the `AWSPowerShell` module, which only supports Windows PowerShell. Also, be sure to use version 3.3.270.0 or newer of `AWSPowerShell.NetCore` which optimizes the cmdlet import process. If you use an older version, you'll experience longer cold starts. For more information, see [AWS Tools for PowerShell](#).

Returning data

Some Lambda invocations are meant to return data back to their caller. For example, if an invocation was in response to a web request coming from API Gateway, then our Lambda function needs to return back the response. For PowerShell Lambda, the last object that's added to the PowerShell pipeline is the return data from the Lambda invocation. If the object is a string, the data is returned as is. Otherwise the object is converted to JSON by using the `ConvertTo-Json` cmdlet.

For example, consider the following PowerShell statement, which adds `$PSVersionTable` to the PowerShell pipeline:

```
$PSVersionTable
```

After the PowerShell script is finished, the last object in the PowerShell pipeline is the return data for the Lambda function. `$PSVersionTable` is a PowerShell global variable that also provides information about the running environment.

Using the Lambda context object to retrieve PowerShell function information

When Lambda runs your function, it passes context information by making a `$LambdaContext` variable available to the [handler](#). This variable provides methods and properties with information about the invocation, function, and execution environment.

Context properties

- `FunctionName` – The name of the Lambda function.
- `FunctionVersion` – The [version](#) of the function.
- `InvokedFunctionArn` – The Amazon Resource Name (ARN) that's used to invoke the function. Indicates if the invoker specified a version number or alias.
- `MemoryLimitInMB` – The amount of memory that's allocated for the function.
- `AwsRequestId` – The identifier of the invocation request.
- `LogGroupName` – The log group for the function.
- `LogStreamName` – The log stream for the function instance.
- `RemainingTime` – The number of milliseconds left before the execution times out.
- `Identity` – (mobile apps) Information about the Amazon Cognito identity that authorized the request.
- `ClientContext` – (mobile apps) Client context that's provided to Lambda by the client application.
- `Logger` – The [logger object](#) for the function.

The following PowerShell code snippet shows a simple handler function that prints some of the context information.

```
#Requires -Modules @{'ModuleName'='AWSPowerShell.NetCore';ModuleVersion='3.3.618.0'}
Write-Host 'Function name:' $LambdaContext.FunctionName
Write-Host 'Remaining milliseconds:' $LambdaContext.RemainingTime.TotalMilliseconds
Write-Host 'Log group name:' $LambdaContext.LogGroupName
Write-Host 'Log stream name:' $LambdaContext.LogStreamName
```

Log and monitor Powershell Lambda functions

AWS Lambda automatically monitors Lambda functions on your behalf and sends logs to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation to the log stream, and relays logs and other output from your function's code. For more information, see [Sending Lambda function logs to CloudWatch Logs](#).

This page describes how to produce log output from your Lambda function's code, and access logs using the AWS Command Line Interface, the Lambda console, or the CloudWatch console.

Sections

- [Creating a function that returns logs](#)
- [Viewing logs in the Lambda console](#)
- [Viewing logs in the CloudWatch console](#)
- [Viewing logs using the AWS Command Line Interface \(AWS CLI\)](#)
- [Deleting logs](#)

Creating a function that returns logs

To output logs from your function code, you can use cmdlets on [Microsoft.PowerShell.Utility](#), or any logging module that writes to stdout or stderr. The following example uses Write-Host.

Example [function/Handler.ps1](#) – Logging

```
#Requires -Modules @{ModuleName='AWSPowerShell.NetCore';ModuleVersion='3.3.618.0'}
Write-Host `## Environment variables
Write-Host AWS_LAMBDA_FUNCTION_VERSION=$Env:AWS_LAMBDA_FUNCTION_VERSION
Write-Host AWS_LAMBDA_LOG_GROUP_NAME=$Env:AWS_LAMBDA_LOG_GROUP_NAME
Write-Host AWS_LAMBDA_LOG_STREAM_NAME=$Env:AWS_LAMBDA_LOG_STREAM_NAME
Write-Host AWS_EXECUTION_ENV=$Env:AWS_EXECUTION_ENV
Write-Host AWS_LAMBDA_FUNCTION_NAME=$Env:AWS_LAMBDA_FUNCTION_NAME
Write-Host PATH=$Env:PATH
Write-Host `## Event
Write-Host (ConvertTo-Json -InputObject $LambdaInput -Compress -Depth 3)
```

Example log format

```
START RequestId: 56639408-xmpl-435f-9041-ac47ae25ceed Version: $LATEST
```

```

```

The .NET runtime logs the START, END, and REPORT lines for each invocation. The report line provides the following details.

REPORT line data fields

- **RequestId** – The unique request ID for the invocation.
- **Duration** – The amount of time that your function's handler method spent processing the event.
- **Billed Duration** – The amount of time billed for the invocation.
- **Memory Size** – The amount of memory allocated to the function.

- **Max Memory Used** – The amount of memory used by the function. When invocations share an execution environment, Lambda reports the maximum memory used across all invocations. This behavior might result in a higher than expected reported value.
- **Init Duration** – For the first request served, the amount of time it took the runtime to load the function and run code outside of the handler method.
- **XRAY TraceId** – For traced requests, the [AWS X-Ray trace ID](#).
- **SegmentId** – For traced requests, the X-Ray segment ID.
- **Sampled** – For traced requests, the sampling result.

Viewing logs in the Lambda console

You can use the Lambda console to view log output after you invoke a Lambda function.

If your code can be tested from the embedded **Code** editor, you will find logs in the **execution results**. When you use the console test feature to invoke a function, you'll find **Log output** in the **Details** section.

Viewing logs in the CloudWatch console

You can use the Amazon CloudWatch console to view logs for all Lambda function invocations.

To view logs on the CloudWatch console

1. Open the [Log groups page](#) on the CloudWatch console.
2. Choose the log group for your function (`/aws/lambda/your-function-name`).
3. Choose a log stream.

Each log stream corresponds to an [instance of your function](#). A log stream appears when you update your Lambda function, and when additional instances are created to handle concurrent invocations. To find logs for a specific invocation, we recommend instrumenting your function with AWS X-Ray. X-Ray records details about the request and the log stream in the trace.

Viewing logs using the AWS Command Line Interface (AWS CLI)

The AWS CLI is an open-source tool that enables you to interact with AWS services using commands in your command line shell. To complete the steps in this section, you must have the [AWS CLI version 2](#).

You can use the [AWS CLI](#) to retrieve logs for an invocation using the `--log-type` command option. The response contains a `LogResult` field that contains up to 4 KB of base64-encoded logs from the invocation.

Example retrieve a log ID

The following example shows how to retrieve a *log ID* from the `LogResult` field for a function named `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail
```

You should see the following output:

```
{
  "StatusCode": 200,
  "LogResult":
    "U1RBULQgUmVxdWVzdElk0iA4N2QwNDRI0C1mMTU0LTExZTgt0GNkYS0yOTc0YzVlNGZiMjEgVmVyc2lvb...",
  "ExecutedVersion": "$LATEST"
}
```

Example decode the logs

In the same command prompt, use the `base64` utility to decode the logs. The following example shows how to retrieve base64-encoded logs for `my-function`.

```
aws lambda invoke --function-name my-function out --log-type Tail \
--query 'LogResult' --output text --cli-binary-format raw-in-base64-out | base64 --
decode
```

The **`cli-binary-format`** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

You should see the following output:

```
START RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8 Version: $LATEST
"AWS_SESSION_TOKEN": "AgoJb3JpZ2luX2VjELj...", "_X_AMZN_TRACE_ID": "Root=1-5d02e5ca-
f5792818b6fe8368e5b51d50;Parent=191db58857df8395;Sampled=0","",ask/lib:/opt/lib",
```

```
END RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8
REPORT RequestId: 57f231fb-1730-4395-85cb-4f71bd2b87b8  Duration: 79.67 ms      Billed
      Duration: 80 ms      Memory Size: 128 MB      Max Memory Used: 73 MB
```

The base64 utility is available on Linux, macOS, and [Ubuntu on Windows](#). macOS users may need to use `base64 -D`.

Example get-logs.sh script

In the same command prompt, use the following script to download the last five log events. The script uses `sed` to remove quotes from the output file, and sleeps for 15 seconds to allow time for the logs to become available. The output includes the response from Lambda and the output from the `get-log-events` command.

Copy the contents of the following code sample and save in your Lambda project directory as `get-logs.sh`.

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

```
#!/bin/bash
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --
payload '{"key": "value"}' out
sed -i'' -e 's/"//g' out
sleep 15
aws logs get-log-events --log-group-name /aws/lambda/my-function --log-stream-
name stream1 --limit 5
```

Example macOS and Linux (only)

In the same command prompt, macOS and Linux users may need to run the following command to ensure the script is executable.

```
chmod -R 755 get-logs.sh
```

Example retrieve the last five log events

In the same command prompt, run the following script to get the last five log events.

```
./get-logs.sh
```

You should see the following output:

```
{
  "StatusCode": 200,
  "ExecutedVersion": "$LATEST"
}
{
  "events": [
    {
      "timestamp": 1559763003171,

Deleting logs

Log groups aren't deleted automatically when you delete a function. To avoid storing logs indefinitely, delete the log group, or [configure a retention period](#) after which logs are deleted automatically.

Building Lambda functions with Rust

Because Rust compiles to native code, you don't need a dedicated runtime to run Rust code on Lambda. Instead, use the [Rust runtime client](#) to build your project locally, and then deploy it to Lambda using an [OS-only runtime](#). When you use an OS-only runtime, Lambda automatically keeps the operating system up to date with the latest patches.

Tools and libraries for Rust

- [AWS SDK for Rust](#): The AWS SDK for Rust provides Rust APIs to interact with Amazon Web Services infrastructure services.
- [Rust runtime client for Lambda](#): The Rust runtime client makes it easy to run Lambda functions written in Rust.
- [Cargo Lambda](#): This is a third-party open-source extension to the Cargo command-line tool that simplifies building and deploying Rust Lambda functions.
- [Lambda HTTP](#): This library provides a wrapper to work with HTTP events.
- [Lambda Extension](#): This library provides support to write Lambda Extensions with Rust.
- [AWS Lambda Events](#): This library provides type definitions for common event source integrations.

Sample Lambda applications for Rust

- [Basic Lambda function](#): A Rust function that shows how to process basic events.
- [Lambda function with error handling](#): A Rust function that shows how to handle custom Rust errors in Lambda.
- [Lambda function with shared resources](#): A Rust project that initializes shared resources before creating the Lambda function.
- [Lambda HTTP events](#): A Rust function that handles HTTP events.
- [Lambda HTTP events with CORS headers](#): A Rust function that uses Tower to inject CORS headers.
- [Lambda REST API](#): A REST API that uses Axum and Diesel to connect to a PostgreSQL database.
- [Serverless Rust demo](#): A Rust project that shows the use of Lambda's Rust libraries, logging, environment variables, and the AWS SDK.
- [Basic Lambda Extension](#): A Rust extension that shows how to process basic extension events.

- [Lambda Logs Amazon Data Firehose Extension](#): A Rust extension that shows how to send Lambda logs to Firehose.

Define Lambda function handlers in Rust

The Lambda function *handler* is the method in your function code that processes events. When your function is invoked, Lambda runs the handler method. Your function runs until the handler returns a response, exits, or times out.

This page describes how to work with Lambda function handlers in Rust, including project initialization, naming conventions, and best practices. This page also includes an example of a Rust Lambda function that takes in information about an order, produces a text file receipt, and puts this file in an Amazon Simple Storage Service (S3) bucket. For more information about how to deploy your function after writing it, see [the section called “Deploy .zip file archives”](#).

Setting up your Rust handler project

When working with Lambda functions in Rust, the process involves writing your code, compiling it, and deploying the compiled artifacts to Lambda. The simplest way to set up a Lambda handler project in Rust is to use the [AWS Lambda Runtime for Rust](#). Despite its name, the AWS Lambda Runtime for Rust is not a managed runtime in the same sense as it is in Lambda for Python, Java, or Node.js. Instead, the AWS Lambda Runtime for Rust is a crate (`lambda_runtime`) that supports writing Lambda functions in Rust and interfacing with AWS Lambda's execution environment.

Use the following command to install [Cargo Lambda](#), a third-party open-source extension to the Cargo command-line tool that simplifies building and deploying Rust Lambda functions:

```
cargo install cargo-lambda
```

After you successfully install `cargo-lambda`, use the following command to initialize a new Rust Lambda function handler project:

```
cargo lambda new example-rust
```

When you run this command, the command line interface (CLI) asks you a couple of questions about your Lambda function:

- **HTTP function** – If you intend to invoke your function via [API Gateway](#) or a [function URL](#), answer **Yes**. Otherwise, answer **No**. In the example code on this page, we invoke our function with a custom JSON event, so we answer **No**.
- **Event type** – If you intend to use a predefined event shape to invoke your function, select the correct expected event type. Otherwise, leave this option blank. In the example code on this page, we invoke our function with a custom JSON event, so we leave this option blank.

After the command runs successfully, enter the main directory of your project:

```
cd example-rust
```

This command generates a `generic_handler.rs` file and a `main.rs` file in the `src` directory. The `generic_handler.rs` can be used to customize a generic event handler. The `main.rs` file contains your main application logic. The `Cargo.toml` file contains metadata about your package and lists its external dependencies.

Example Rust Lambda function code

The following example Rust Lambda function code takes in information about an order, produces a text file receipt, and puts this file in an Amazon S3 bucket.

Example `main.rs` Lambda function

```
use aws_sdk_s3::{Client, primitives::ByteStream};
use lambda_runtime::{run, service_fn, Error, LambdaEvent};
use serde::{Deserialize, Serialize};
use serde_json::Value;
use std::env;
```

```
#[derive(Deserialize, Serialize)]
struct Order {
    order_id: String,
    amount: f64,
    item: String,
}

async fn function_handler(event: LambdaEvent<Value>) -> Result<String, Error> {
    let payload = event.payload;

    // Deserialize the incoming event into Order struct
    let order: Order = serde_json::from_value(payload)?;

    let bucket_name = env::var("RECEIPT_BUCKET")
        .map_err(|_| "RECEIPT_BUCKET environment variable is not set")?;

    let receipt_content = format!(
        "OrderID: {}\nAmount: {:.2}\nItem: {}",
        order.order_id, order.amount, order.item
    );
    let key = format!("receipts/{}.txt", order.order_id);

    let config =
aws_config::load_defaults(aws_config::BehaviorVersion::latest()).await;
    let s3_client = Client::new(&config);

    upload_receipt_to_s3(&s3_client, &bucket_name, &key, &receipt_content).await?;

    Ok("Success".to_string())
}

async fn upload_receipt_to_s3(
    client: &Client,
    bucket_name: &str,
    key: &str,
    content: &str,
) -> Result<(), Error> {
    client
        .put_object()
        .bucket(bucket_name)
        .key(key)
        .body(ByteStream::from(content.as_bytes().to_vec())) // Fixed conversion
        .content_type("text/plain")
        .send()
}
```

```
        .await?;

    Ok(())
}

#[tokio::main]
async fn main() -> Result<(), Error> {
    run(service_fn(function_handler)).await
}
```

This `main.rs` file contains the following sections of code:

- **use statements:** Use these to import Rust crates and methods that your Lambda function requires.
- `#[derive(Deserialize, Serialize)]`: Define the shape of the expected input event in this Rust struct.
- `async fn function_handler(event: LambdaEvent<Value>) -> Result<String, Error>`: This is the **main handler method**, which contains your main application logic.
- `async fn upload_receipt_to_s3 (...)`: This is a helper method that's referenced by the main `function_handler` method.
- `#[tokio::main]`: This is a macro that marks the entry point of a Rust program. It also sets up a [Tokio runtime](#), which allows your `main()` method to use `async/await` and run asynchronously.
- `async fn main() -> Result<(), Error>`: The `main()` function is the entry point of your code. Within it, we specify `function_handler` as the main handler method.

Sample Cargo.toml file

The following `Cargo.toml` file accompanies this function.

```
[package]
name = "example-rust"
version = "0.1.0"
edition = "2024"

[dependencies]
aws-config = "1.5.18"
aws-sdk-s3 = "1.78.0"
lambda_runtime = "0.13.0"
serde = { version = "1", features = ["derive"] }
```

```
serde_json = "1"
tokio = { version = "1", features = ["full"] }
```

For this function to work properly, its [execution role](#) must allow the `s3:PutObject` action. Also, ensure that you define the `RECEIPT_BUCKET` environment variable. After a successful invocation, the Amazon S3 bucket should contain a receipt file.

Valid class definitions for Rust handlers

In most cases, Lambda handler signatures that you define in Rust will have the following format:

```
async fn function_handler(event: LambdaEvent<T>) -> Result<U, Error>
```

For this handler:

- The name of this handler is `function_handler`.
- The singular input to the handler is `event`, and is of type `LambdaEvent<T>`.
 - `LambdaEvent` is a wrapper that comes from the `lambda_runtime` crate. Using this wrapper gives you access to the context object, which includes Lambda-specific metadata such as the request ID of the invocation.
 - `T` is the deserialized event type. For example, this can be `serde_json::Value`, which allows the handler to take in any generic JSON input. Alternatively, this can be a type like `ApiGatewayProxyRequest` if your function expects a specific, pre-defined input type.
- The return type of the handler is `Result<U, Error>`.
 - `U` is the deserialized output type. `U` must implement the `serde::Serialize` trait so Lambda can convert the return value to JSON. For example, `U` can be a simple type like `String`, `serde_json::Value`, or a custom struct as long as it implements `Serialize`. When your code reaches an `Ok(U)` statement, this indicates successful execution, and your function returns a value of type `U`.
 - When your code encounters an error (i.e. `Err(Error)`), your function logs the error in Amazon CloudWatch and returns an error response of type `Error`.

In our example, the handler signature looks like the following:

```
async fn function_handler(event: LambdaEvent<Value>) -> Result<String, Error>
```

Other valid handler signatures can feature the following:

- Omitting the `LambdaEvent` wrapper – If you omit `LambdaEvent`, you lose access to the Lambda context object within your function. The following is an example of this type of signature:

```
async fn handler(event: serde_json::Value) -> Result<String, Error>
```

- Using the unit type as an input – For Rust, you can use the unit type to represent an empty input. This is commonly used for functions with periodic, scheduled invocations. The following is an example of this type of signature:

```
async fn handler(_: ()) -> Result<Value, Error>
```

Handler naming conventions

Lambda handlers in Rust don't have strict naming restrictions. Although you can use any name for your handler, function names in Rust are generally in `snake_case`.

For smaller applications, such as in this example, you can use a single `main.rs` file to contain all of your code. For larger projects, `main.rs` should contain the entry point to your function, but you can have additional files for that separate your code into logical modules. For example, you might have the following file structure:

```
/example-rust
### src/
#   ### main.rs           # Entry point
#   ### handler.rs       # Contains main handler
#   ### services.rs      # [Optional] Back-end service calls
#   ### models.rs        # [Optional] Data models
### Cargo.toml
```

Defining and accessing the input event object

JSON is the most common and standard input format for Lambda functions. In this example, the function expects an input similar to the following:

```
{
  "order_id": "12345",
  "amount": 199.99,
```

```
"item": "Wireless Headphones"
}
```

In Rust, you can define the shape of the expected input event in a struct. In this example, we define the following struct to represent an Order:

```
#[derive(Deserialize, Serialize)]
struct Order {
    order_id: String,
    amount: f64,
    item: String,
}
```

This struct matches the expected input shape. In this example, the `#[derive(Deserialize, Serialize)]` macro automatically generates code for serialization and deserialization. This means that we can deserialize the generic input JSON type into our struct using the `serde_json::from_value()` method. This is illustrated in the first few lines of the handler:

```
async fn function_handler(event: LambdaEvent<Value>) -> Result<String, Error> {
    let payload = event.payload;

    // Deserialize the incoming event into Order struct
    let order: Order = serde_json::from_value(payload)?;
    ...
}
```

You can then access the fields of the object. For example, `order.order_id` retrieves the value of `order_id` from the original input.

Pre-defined input event types

There are many pre-defined input event types available in the `aws_lambda_events` crate. For example, if you intend to invoke your function with API Gateway, including the following import:

```
use aws_lambda_events::event::apigw::ApiGatewayProxyRequest;
```

Then, make sure your main handler uses the following signature:

```
async fn handler(event: LambdaEvent<ApiGatewayProxyRequest>) -> Result<String, Error> {
    let body = event.payload.body.unwrap_or_default();
}
```

```
    ...  
}
```

Refer to the [aws_lambda_events crate](#) for more information about other pre-defined input event types.

Accessing and using the Lambda context object

The Lambda [context object](#) contains information about the invocation, function, and execution environment. In Rust, the `LambdaEvent` wrapper includes the context object. For example, you can use the context object to retrieve the request ID of the current invocation with the following code:

```
async fn function_handler(event: LambdaEvent<Value>) -> Result<String, Error> {  
    let request_id = event.context.request_id;  
    ...  
}
```

For more information about the context object, see [the section called "Context"](#).

Using the AWS SDK for Rust in your handler

Often, you'll use Lambda functions to interact with or make updates to other AWS resources. The simplest way to interface with these resources is to use the [AWS SDK for Rust](#).

To add SDK dependencies to your function, add them in your `Cargo.toml` file. We recommend only adding the libraries that you need for your function. In the example code earlier, we used the `aws_sdk_s3::Client`. In the `Cargo.toml` file, you can add this dependency by adding the following line under the `[dependencies]` section:

```
aws-sdk-s3 = "1.78.0"
```

Note

This may not be the most recent version. Choose the appropriate version for your application.

The, import the dependencies directly in your code:

```
use aws_sdk_s3::{Client, primitives::ByteStream};
```

The example code then initializes an Amazon S3 client as follows:

```
let config = aws_config::load_defaults(aws_config::BehaviorVersion::latest()).await;  
let s3_client = Client::new(&config);
```

After you initialize your SDK client, you can then use it to interact with other AWS services. The example code calls the Amazon S3 PutObject API in the `upload_receipt_to_s3` helper function.

Accessing environment variables

In your handler code, you can reference any [environment variables](#) by using the `env::var` method. In this example, we reference the defined `RECEIPT_BUCKET` environment variable using the following line of code:

```
let bucket_name = env::var("RECEIPT_BUCKET")  
    .map_err(|_| "RECEIPT_BUCKET environment variable is not set")?;
```

Using shared state

You can declare shared variables that are independent of your Lambda function's handler code. These variables can help you load state information during the [Init phase](#), before your function receives any events. For example, you can modify the code on this page to use shared state when initializing the Amazon S3 client by updating the main function and handler signature:

```
async fn function_handler(client: &Client, event: LambdaEvent<Value>) -> Result<String,  
    Error> {  
    ...  
    upload_receipt_to_s3(client, &bucket_name, &key, &receipt_content).await?;  
    ...  
}  
  
...  
  
#[tokio::main]  
async fn main() -> Result<(), Error> {  
    let shared_config = aws_config::from_env().load().await;
```

```
let client = Client::new(&shared_config);
let shared_client = &client;
lambda_runtime::run(service_fn(move |event: LambdaEvent<Request>| async move {
    handler(&shared_client, event).await
})))
.await
```

Code best practices for Rust Lambda functions

Adhere to the guidelines in the following list to use best coding practices when building your Lambda functions:

- **Separate the Lambda handler from your core logic.** This allows you to make a more unit-testable function.
- **Minimize the complexity of your dependencies.** Prefer simpler frameworks that load quickly on [execution environment](#) startup.
- **Minimize your deployment package size to its runtime necessities.** This will reduce the amount of time that it takes for your deployment package to be downloaded and unpacked ahead of invocation.

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

Using the Lambda context object to retrieve Rust function information

When Lambda runs your function, it adds a context object to the `LambdaEvent` that the [handler](#) receives. This object provides properties with information about the invocation, function, and execution environment.

Context properties

- `request_id`: The AWS request ID generated by the Lambda service.
- `deadline`: The execution deadline for the current invocation in milliseconds.
- `invoked_function_arn`: The Amazon Resource Name (ARN) of the Lambda function being invoked.
- `xray_trace_id`: The AWS X-Ray trace ID for the current invocation.
- `client_content`: The client context object sent by the AWS mobile SDK. This field is empty unless the function is invoked using an AWS mobile SDK.
- `identity`: The Amazon Cognito identity that invoked the function. This field is empty unless the invocation request to the Lambda APIs was made using AWS credentials issued by Amazon Cognito identity pools.
- `env_config`: The Lambda function configuration from the local environment variables. This property includes information such as the function name, memory allocation, version, and log streams.

Accessing invoke context information

Lambda functions have access to metadata about their environment and the invocation request. The `LambdaEvent` object that your function handler receives includes the context metadata:

```
use lambda_runtime::{service_fn, LambdaEvent, Error};
use serde_json::{json, Value};

async fn handler(event: LambdaEvent<Value>) -> Result<Value, Error> {
    let invoked_function_arn = event.context.invoked_function_arn;
    Ok(json!({ "message": format!("Hello, this is function {invoked_function_arn}!") }))
}
```

```
#[tokio::main]
async fn main() -> Result<(), Error> {
    lambda_runtime::run(service_fn(handler)).await
}
```

Processing HTTP events with Rust

Amazon API Gateway APIs, Application Load Balancers, and [Lambda function URLs](#) can send HTTP events to Lambda. You can use the [aws_lambda_events](#) crate from crates.io to process events from these sources.

Example— Handle API Gateway proxy request

Note the following:

- use `aws_lambda_events::apigw::{ApiGatewayProxyRequest, ApiGatewayProxyResponse}`: The [aws_lambda_events](#) crate includes many Lambda events. To reduce compilation time, use feature flags to activate the events you need. Example:
`aws_lambda_events = { version = "0.8.3", default-features = false, features = ["apigw"] }`.
- use `http::HeaderMap`: This import requires you to add the [http](#) crate to your dependencies.

```
use aws_lambda_events::apigw::{ApiGatewayProxyRequest, ApiGatewayProxyResponse};
use http::HeaderMap;
use lambda_runtime::{service_fn, Error, LambdaEvent};

async fn handler(
    _event: LambdaEvent<ApiGatewayProxyRequest>,
) -> Result<ApiGatewayProxyResponse, Error> {
    let mut headers = HeaderMap::new();
    headers.insert("content-type", "text/html".parse().unwrap());
    let resp = ApiGatewayProxyResponse {
        status_code: 200,
        multi_value_headers: headers.clone(),
        is_base64_encoded: false,
        body: Some("Hello AWS Lambda HTTP request".into()),
        headers,
    };
    Ok(resp)
}

#[tokio::main]
async fn main() -> Result<(), Error> {
    lambda_runtime::run(service_fn(handler)).await
}
```

The [Rust runtime client for Lambda](#) also provides an abstraction over these event types that allows you to work with native HTTP types, regardless of which service sends the events. The following code is equivalent to the previous example, and it works out of the box with Lambda function URLs, Application Load Balancers, and API Gateway.

Note

The [lambda_http](#) crate uses the [lambda_runtime](#) crate underneath. You don't have to import `lambda_runtime` separately.

Example— Handle HTTP requests

```
use lambda_http::{service_fn, Error, IntoResponse, Request, RequestExt, Response};

async fn handler(event: Request) -> Result<impl IntoResponse, Error> {
    let resp = Response::builder()
        .status(200)
        .header("content-type", "text/html")
        .body("Hello AWS Lambda HTTP request")
        .map_err(Box::new)?;
    Ok(resp)
}

#[tokio::main]
async fn main() -> Result<(), Error> {
    lambda_http::run(service_fn(handler)).await
}
```

For another example of how to use `lambda_http`, see the [http-axum code sample](#) on the AWS Labs GitHub repository.

Sample HTTP Lambda events for Rust

- [Lambda HTTP events](#): A Rust function that handles HTTP events.
- [Lambda HTTP events with CORS headers](#): A Rust function that uses Tower to inject CORS headers.
- [Lambda HTTP events with shared resources](#): A Rust function that uses shared resources initialized before the function handler is created.

Deploy Rust Lambda functions with .zip file archives

This page describes how to compile your Rust function, and then deploy the compiled binary to AWS Lambda using [Cargo Lambda](#). It also shows how to deploy the compiled binary with the AWS Command Line Interface and the AWS Serverless Application Model CLI.

Sections

- [Prerequisites](#)
- [Building Rust functions on macOS, Windows, or Linux](#)
- [Deploying the Rust function binary with Cargo Lambda](#)
- [Invoking your Rust function with Cargo Lambda](#)

Prerequisites

- [Rust](#)
- [AWS CLI version 2](#)

Building Rust functions on macOS, Windows, or Linux

The following steps demonstrate how to create the project for your first Lambda function with Rust and compile it with [Cargo Lambda](#), a third-party open-source extension to the Cargo command-line tool that simplifies building and deploying Rust Lambda functions.

1. Install [Cargo Lambda](#), a third-party open-source extension to the Cargo command-line tool that simplifies building and deploying Rust Lambda functions:

```
cargo install cargo-lambda
```

For other installation options, see [Installation](#) in the Cargo Lambda documentation.

2. Create the package structure. This command creates some basic function code in `src/main.rs`. You can use this code for testing or replace it with your own.

```
cargo lambda new my-function
```

3. Inside the package's root directory, run the [build](#) subcommand to compile the code in your function.

```
cargo lambda build --release
```

(Optional) If you want to use AWS Graviton2 on Lambda, add the `--arm64` flag to compile your code for ARM CPUs.

```
cargo lambda build --release --arm64
```

4. Before deploying your Rust function, configure AWS credentials on your machine.

```
aws configure
```

Deploying the Rust function binary with Cargo Lambda

Use the [deploy](#) subcommand to deploy the compiled binary to Lambda. This command creates an [execution role](#) and then creates the Lambda function. To specify an existing execution role, use the [--iam-role](#) flag.

```
cargo lambda deploy my-function
```

Deploying your Rust function binary with the AWS CLI

You can also deploy your binary with the AWS CLI.

1. Use the [build](#) subcommand to build the .zip deployment package.

```
cargo lambda build --release --output-format zip
```

2. To deploy the .zip package to Lambda, run the [create-function](#) command.
 - For `--runtime`, specify `provided.al2023`. This is an [OS-only runtime](#). OS-only runtimes are used to deploy compiled binaries and custom runtimes to Lambda.
 - For `--role`, specify the ARN of the [execution role](#).

```
aws lambda create-function \  
  --function-name my-function \  
  --runtime provided.al2023 \  
  --role arn:aws:iam::111122223333:role/lambda-role \  
  --zip-file fileb://my-function.zip
```

```
--handler rust.handler \  
--zip-file fileb://target/lambda/my-function/bootstrap.zip
```

Deploying your Rust function binary with the AWS SAM CLI

You can also deploy your binary with the AWS SAM CLI.

1. Create an AWS SAM template with the resource and property definition. For Runtime, specify `provided.al2023`. This is an [OS-only runtime](#). OS-only runtimes are used to deploy compiled binaries and custom runtimes to Lambda.

For more information about deploying Lambda functions using AWS SAM, see [AWS::Serverless::Function](#) in the *AWS Serverless Application Model Developer Guide*.

Example SAM resource and property definition for a Rust binary

```
AWSTemplateFormatVersion: '2010-09-09'  
Transform: AWS::Serverless-2016-10-31  
Description: SAM template for Rust binaries  
Resources:  
  RustFunction:  
    Type: AWS::Serverless::Function  
    Properties:  
      CodeUri: target/lambda/my-function/  
      Handler: rust.handler  
      Runtime: provided.al2023  
Outputs:  
  RustFunction:  
    Description: "Lambda Function ARN"  
    Value: !GetAtt RustFunction.Arn
```

2. Use the [build](#) subcommand to compile the function.

```
cargo lambda build --release
```

3. Use the [sam deploy](#) command to deploy the function to Lambda.

```
sam deploy --guided
```

For more information about building Rust functions with the AWS SAM CLI, see [Building Rust Lambda functions with Cargo Lambda](#) in the *AWS Serverless Application Model Developer Guide*.

Invoking your Rust function with Cargo Lambda

Use the [invoke](#) subcommand to test your function with a payload.

```
cargo lambda invoke --remote --data-ascii '{"command": "Hello world"}' my-function
```

Invoking your Rust function with the AWS CLI

You can also use the AWS CLI to invoke the function.

```
aws lambda invoke --function-name my-function --cli-binary-format raw-in-base64-out --  
payload '{"command": "Hello world"}' /tmp/out.txt
```

The **cli-binary-format** option is required if you're using AWS CLI version 2. To make this the default setting, run `aws configure set cli-binary-format raw-in-base64-out`. For more information, see [AWS CLI supported global command line options](#) in the *AWS Command Line Interface User Guide for Version 2*.

Working with layers for Rust Lambda functions

We don't recommend using [layers](#) to manage dependencies for Lambda functions written in Rust. This is because Lambda functions in Rust compile into a single executable, which you provide to Lambda when you deploy your function. This executable contains your compiled function code, along with all of its dependencies. Using layers not only complicates this process, but also leads to increased cold start times because your functions need to manually load extra assemblies into memory during the init phase.

To use external dependencies with your Rust handlers, include them directly in your deployment package. By doing so, you simplify the deployment process and also take advantage of built-in Rust compiler optimizations. For an example of how to import and use a dependency like the AWS SDK for Rust in your function, see [the section called "Handler"](#).

Log and monitor Rust Lambda functions

AWS Lambda automatically monitors Lambda functions on your behalf and sends logs to Amazon CloudWatch. Your Lambda function comes with a CloudWatch Logs log group and a log stream for each instance of your function. The Lambda runtime environment sends details about each invocation to the log stream, and relays logs and other output from your function's code. For more information, see [Sending Lambda function logs to CloudWatch Logs](#). For information about configuring log formats, see [Configuring JSON and plain text log formats](#). This page describes how to produce log output from your Lambda function's code.

Creating a function that writes logs

To output logs from your function code, you can use any logging function that writes to `stdout` or `stderr`, such as the `println!` macro. The following example uses `println!` to print a message when the function handler starts and before it finishes.

```
use lambda_runtime::{service_fn, LambdaEvent, Error};
use serde_json::{json, Value};
async fn handler(event: LambdaEvent<Value>) -> Result<Value, Error> {
    println!("Rust function invoked");
    let payload = event.payload;
    let first_name = payload["firstName"].as_str().unwrap_or("world");
    println!("Rust function responds to {}", &first_name);
    Ok(json!({ "message": format!("Hello, {}!", first_name) }))
}

#[tokio::main]
async fn main() -> Result<(), Error> {
    lambda_runtime::run(service_fn(handler)).await
}
```

Implementing advanced logging with the Tracing crate

[Tracing](#) is a framework for instrumenting Rust programs to collect structured, event-based diagnostic information. This framework provides utilities to customize logging output levels and formats, like creating structured JSON log messages. To use this framework, you must initialize a subscriber before implementing the function handler. Then, you can use tracing macros like `debug`, `info`, and `error`, to specify the level of logging that you want for each scenario.

Example— Using the Tracing crate

Note the following:

- `tracing_subscriber::fmt().json()`: When this option is included, logs are formatted in JSON. To use this option, you must include the `json` feature in the `tracing-subscriber` dependency (for example, `tracing-subscriber = { version = "0.3.11", features = ["json"] }`).
- `#[tracing::instrument(skip(event), fields(req_id = %event.context.request_id))]`: This annotation generates a span every time the handler is invoked. The span adds the request ID to each log line.
- `{ %first_name }`: This construct adds the `first_name` field to the log line where it's used. The value for this field corresponds to the variable with the same name.

```
use lambda_runtime::{service_fn, Error, LambdaEvent};
use serde_json::{json, Value};
#[tracing::instrument(skip(event), fields(req_id = %event.context.request_id))]
async fn handler(event: LambdaEvent<Value>) -> Result<Value, Error> {
    tracing::info!("Rust function invoked");
    let payload = event.payload;
    let first_name = payload["firstName"].as_str().unwrap_or("world");
    tracing::info!({ %first_name }, "Rust function responds to event");
    Ok(json!({ "message": format!("Hello, {first_name}!") }))
}

#[tokio::main]
async fn main() -> Result<(), Error> {
    tracing_subscriber::fmt().json()
        .with_max_level(tracing::Level::INFO)
        // this needs to be set to remove duplicated information in the log.
        .with_current_span(false)
        // this needs to be set to false, otherwise ANSI color codes will
        // show up in a confusing manner in CloudWatch logs.
        .with_ansi(false)
        // disabling time is handy because CloudWatch will add the ingestion time.
        .without_time()
        // remove the name of the function from every log entry
        .with_target(false)
        .init();
    lambda_runtime::run(service_fn(handler)).await
}
```

```
}
```

When this Rust function is invoked, it prints two log lines similar to the following:

```
{"level":"INFO","fields":{"message":"Rust function invoked"},"spans":  
[{"req_id":"45daaaa7-1a72-470c-9a62-e79860044bb5","name":"handler"}]}  
{"level":"INFO","fields":{"message":"Rust function responds to  
event","first_name":"David"},"spans":[{"req_id":"45daaaa7-1a72-470c-9a62-  
e79860044bb5","name":"handler"}]}
```

Best practices for working with AWS Lambda functions

The following are recommended best practices for using AWS Lambda:

Topics

- [Function code](#)
- [Function configuration](#)
- [Function scalability](#)
- [Metrics and alarms](#)
- [Working with streams](#)
- [Security best practices](#)

Function code

Take advantage of execution environment reuse to improve the performance of your function.

Initialize SDK clients and database connections outside of the function handler, and cache static assets locally in the /tmp directory. Subsequent invocations processed by the same instance of your function can reuse these resources. This saves cost by reducing function run time.

To avoid potential data leaks across invocations, don't use the execution environment to store user data, events, or other information with security implications. If your function relies on a mutable state that can't be stored in memory within the handler, consider creating a separate function or separate versions of a function for each user.

Use a keep-alive directive to maintain persistent connections. Lambda purges idle connections over time. Attempting to reuse an idle connection when invoking a function will result in a connection error. To maintain your persistent connection, use the keep-alive directive associated with your runtime. For an example, see [Reusing Connections with Keep-Alive in Node.js](#).

Use [environment variables](#) to pass operational parameters to your function. For example, if you are writing to an Amazon S3 bucket, instead of hard-coding the bucket name you are writing to, configure the bucket name as an environment variable.

Avoid using recursive invocations in your Lambda function, where the function invokes itself or initiates a process that may invoke the function again. This could lead to unintended volume of function invocations and escalated costs. If you see an unintended volume of invocations, set the

function reserved concurrency to 0 immediately to throttle all invocations to the function, while you update the code.

Do not use non-documented, non-public APIs in your Lambda function code. For AWS Lambda managed runtimes, Lambda periodically applies security and functional updates to Lambda's internal APIs. These internal API updates may be backwards-incompatible, leading to unintended consequences such as invocation failures if your function has a dependency on these non-public APIs. See [the API reference](#) for a list of publicly available APIs.

Write idempotent code. Writing idempotent code for your functions ensures that duplicate events are handled the same way. Your code should properly validate events and gracefully handle duplicate events. For more information, see [How do I make my Lambda function idempotent?](#).

 **Note**

You can use Powertools for AWS Lambda to make functions idempotent. For more information, see:

- [Python - Idempotency utility](#)
- [TypeScript - Idempotency utility](#)
- [Java - Idempotency utility](#)
- [.NET - Idempotency utility](#)

For language-specific code best practices, refer to the following sections:

- [Code best practices for Node.js Lambda functions](#)
- [Code best practices for TypeScript Lambda functions](#)
- [Code best practices for Python Lambda functions](#)
- [Code best practices for Ruby Lambda functions](#)
- [Code best practices for Java Lambda functions](#)
- [Code best practices for Go Lambda functions](#)
- [Code best practices for C# Lambda functions](#)
- [Code best practices for Rust Lambda functions](#)

Function configuration

Performance testing your Lambda function is a crucial part in ensuring you pick the optimum memory size configuration. Any increase in memory size triggers an equivalent increase in CPU available to your function. The memory usage for your function is determined per-invoke and can be viewed in [Amazon CloudWatch](#). On each invoke a `REPORT :` entry will be made, as shown below:

```
REPORT RequestId: 3604209a-e9a3-11e6-939a-754dd98c7be3 Duration: 12.34 ms Billed
Duration: 100 ms Memory Size: 128 MB Max Memory Used: 18 MB
```

By analyzing the `Max Memory Used :` field, you can determine if your function needs more memory or if you over-provisioned your function's memory size.

To find the right memory configuration for your functions, we recommend using the open source AWS Lambda Power Tuning project. For more information, see [AWS Lambda Power Tuning](#) on GitHub.

To optimize function performance, we also recommend deploying libraries that can leverage Advanced Vector Extensions 2 (AVX2). This allows you to process demanding workloads, including machine learning inferencing, media processing, high performance computing (HPC), scientific simulations, and financial modeling. For more information, see [Creating faster AWS Lambda functions with AVX2](#).

Load test your Lambda function to determine an optimum timeout value. It is important to analyze how long your function runs so that you can better determine any problems with a dependency service that may increase the concurrency of the function beyond what you expect. This is especially important when your Lambda function makes network calls to resources that may not handle Lambda's scaling. For more information about load testing your application, see [Distributed Load Testing on AWS](#).

Use most-restrictive permissions when setting IAM policies. Understand the resources and operations your Lambda function needs, and limit the execution role to these permissions. For more information, see [Managing permissions in AWS Lambda](#).

Be familiar with [Lambda quotas](#). Payload size, file descriptors and `/tmp` space are often overlooked when determining runtime resource limits.

Delete Lambda functions that you are no longer using. By doing so, the unused functions won't needlessly count against your deployment package size limit.

If you are using Amazon Simple Queue Service as an event source, make sure the value of the function's expected invocation time does not exceed the [Visibility Timeout](#) value on the queue. This applies both to [CreateFunction](#) and [UpdateFunctionConfiguration](#).

- In the case of **CreateFunction**, AWS Lambda will fail the function creation process.
- In the case of **UpdateFunctionConfiguration**, it could result in duplicate invocations of the function.

Function scalability

Be familiar with your upstream and downstream throughput constraints. While Lambda functions scale seamlessly with load, upstream and downstream dependencies may not have the same throughput capabilities. If you need to limit how high your function can scale, you can [configure reserved concurrency](#) on your function.

Build in throttle tolerance. If your synchronous function experiences throttling due to traffic exceeding Lambda's scaling rate, you can use the following strategies to improve throttle tolerance:

- Use [timeouts, retries, and backoff with jitter](#). Implementing these strategies smooth out retried invocations, and helps ensure Lambda can scale up within seconds to minimize end-user throttling.
- Use [provisioned concurrency](#). Provisioned concurrency is the number of pre-initialized execution environments that Lambda allocates to your function. Lambda handles incoming requests using provisioned concurrency when available. Lambda can also scale your function above and beyond your provisioned concurrency setting if required. Configuring provisioned concurrency incurs additional charges to your AWS account.

Metrics and alarms

Use [Using CloudWatch metrics with Lambda](#) and [CloudWatch Alarms](#) instead of creating or updating a metric from within your Lambda function code. It's a much more efficient way to track the health of your Lambda functions, allowing you to catch issues early in the development process. For instance, you can configure an alarm based on the expected duration of your Lambda function invocation in order to address any bottlenecks or latencies attributable to your function code.

Emit custom metrics asynchronously using Embedded Metric Format (EMF). Instead of making synchronous API calls to CloudWatch, use EMF to emit metrics through your function's logs. This approach reduces latency and improves performance. The Metrics utility in Powertools for AWS Lambda handles EMF formatting automatically. For more information, see [Python](#), [TypeScript](#), [Java](#), or [.NET](#) Metrics utilities in the Powertools for AWS Lambda documentation. For information on using EMF to generate metric format logs, see [Publishing logs with the embedded metric format](#) in the Amazon CloudWatch User Guide.

Use structured JSON logging for better observability. Structured logging makes it easier to search, filter, and analyze your function's logs. Consider using the Logger utility from Powertools for AWS Lambda to automatically format logs in JSON. For more information, see [Python](#), [TypeScript](#), [Java](#), or [.NET](#) Logger utilities in the Powertools for AWS Lambda documentation.

Leverage your logging library and [AWS Lambda Metrics and Dimensions](#) to catch app errors (e.g. ERR, ERROR, WARNING, etc.)

Use [AWS Cost Anomaly Detection](#) to detect unusual activity on your account. Cost Anomaly Detection uses machine learning to continuously monitor your cost and usage while minimizing false positive alerts. Cost Anomaly Detection uses data from AWS Cost Explorer, which has a delay of up to 24 hours. As a result, it can take up to 24 hours to detect an anomaly after usage occurs. To get started with Cost Anomaly Detection, you must first [sign up for Cost Explorer](#). Then, [access Cost Anomaly Detection](#).

Working with streams

Test with different batch and record sizes so that the polling frequency of each event source is tuned to how quickly your function is able to complete its task. The [CreateEventSourceMapping](#) BatchSize parameter controls the maximum number of records that can be sent to your function with each invoke. A larger batch size can often more efficiently absorb the invoke overhead across a larger set of records, increasing your throughput.

By default, Lambda invokes your function as soon as records are available. If the batch that Lambda reads from the event source has only one record in it, Lambda sends only one record to the function. To avoid invoking the function with a small number of records, you can tell the event source to buffer records for up to 5 minutes by configuring a *batching window*. Before invoking the function, Lambda continues to read records from the event source until it has gathered a full batch, the batching window expires, or the batch reaches the payload limit of 6 MB. For more information, see [Batching behavior](#).

⚠ Warning

Lambda event source mappings process each event at least once, and duplicate processing of records can occur. To avoid potential issues related to duplicate events, we strongly recommend that you make your function code idempotent. To learn more, see [How do I make my Lambda function idempotent](#) in the AWS Knowledge Center.

Enable partial batch response for stream processing. When processing batches of records from streams like Kinesis or DynamoDB Streams, enable partial batch response to allow Lambda to retry only the failed records instead of the entire batch. This improves processing efficiency and reduces unnecessary reprocessing. You can optionally use the Batch utility from Powertools for AWS Lambda to simplify batch processing patterns.

ℹ Note

You can use Powertools for AWS Lambda for batch processing. For more information, see:

- [Python - Batch Processing](#)
- [TypeScript - Batch Processing](#)
- [Java - Batch Processing](#)
- [.NET - Batch Processing](#)

Increase Kinesis stream processing throughput by adding shards. A Kinesis stream is composed of one or more shards. The rate at which Lambda can read data from Kinesis scales linearly with the number of shards. Increasing the number of shards will directly increase the number of maximum concurrent Lambda function invocations and can increase your Kinesis stream processing throughput. For more information about the relationship between shards and function invocations, see [the section called “Polling and batching streams”](#). If you are increasing the number of shards in a Kinesis stream, make sure you have picked a good partition key (see [Partition Keys](#)) for your data, so that related records end up on the same shards and your data is well distributed.

Use [Amazon CloudWatch](#) on `IteratorAge` to determine if your Kinesis stream is being processed. For example, configure a CloudWatch alarm with a maximum setting to 30000 (30 seconds).

Security best practices

Monitor your usage of AWS Lambda as it relates to security best practices by using AWS Security Hub CSPM. Security Hub CSPM uses security controls to evaluate resource configurations and security standards to help you comply with various compliance frameworks. For more information about using Security Hub CSPM to evaluate Lambda resources, see [AWS Lambda controls](#) in the AWS Security Hub CSPM User Guide.

Monitor Lambda network activity logs using Amazon GuardDuty Lambda Protection. GuardDuty Lambda protection helps you identify potential security threats when Lambda functions are invoked in your AWS account. For example, if one of your functions queries an IP address that is associated with cryptocurrency-related activity. GuardDuty monitors the network activity logs that are generated when a Lambda function is invoked. To learn more, see [Lambda protection](#) in the *Amazon GuardDuty User Guide*.

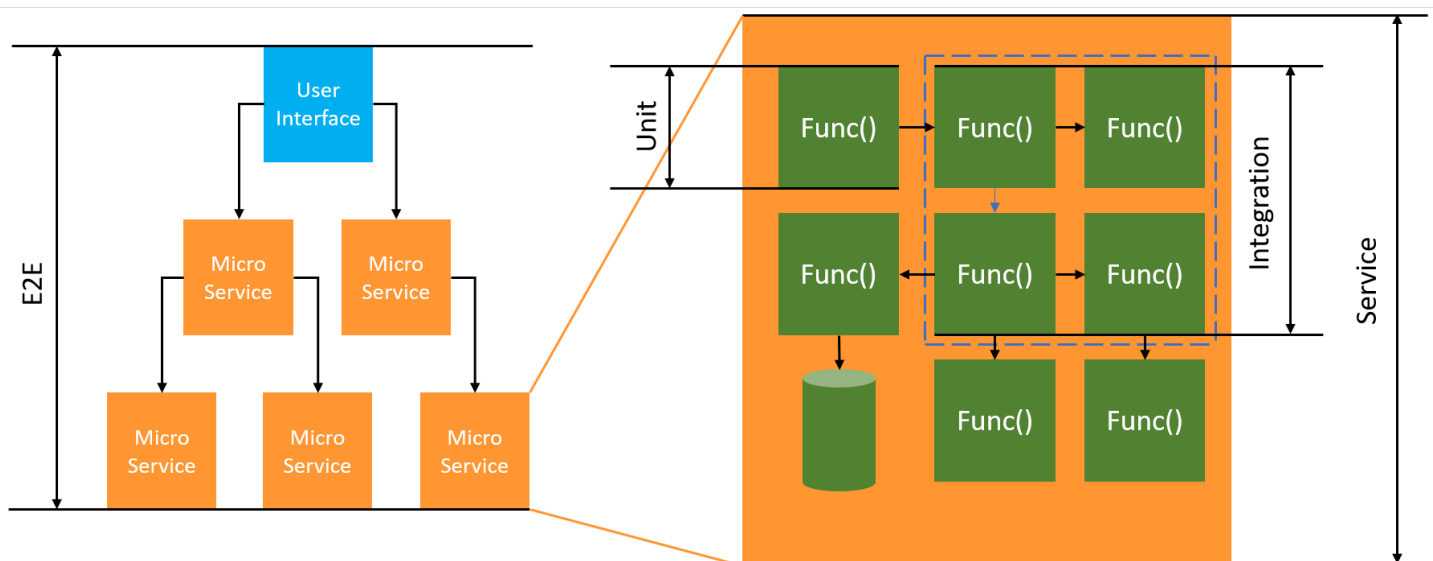

How to test serverless functions and applications

Testing serverless functions uses traditional test types and techniques, but you must also consider testing serverless applications as a whole. Cloud-based tests will provide the **most accurate** measure of quality of both your functions and serverless applications.

A serverless application architecture includes managed services that provide critical application functionality through API calls. For this reason, your development cycle should include automated tests that verify functionality when your function and services interact.

If you do not create cloud-based tests, you could encounter issues due to differences between your local environment and the deployed environment. Your continuous integration process should run tests against a suite of resources provisioned in the cloud before promoting your code to the next deployment environment, such as QA, Staging, or Production.

Continue reading this short guide to learn about testing strategies for serverless applications, or visit the [Serverless Test Samples repository](#) to dive in with practical examples, specific to your chosen language and runtime.

For serverless testing, you will still write *unit*, *integration* and *end-to-end* tests.

- **Unit tests** - Tests that run against an isolated block of code. For example, verifying the business logic to calculate the delivery charge given a particular item and destination.
- **Integration tests** - Tests involving two or more components or services that interact, typically in a cloud environment. For example, verifying a function processes events from a queue.

- **End-to-end tests** - Tests that verify behavior across an entire application. For example, ensuring infrastructure is set up correctly and that events flow between services as expected to record a customer's order.

Targeted business outcomes

Testing serverless solutions may require slightly more time to set up tests that verify event-driven interactions between services. Keep the following practical business reasons in mind as you read this guide:

- Increase the quality of your application
- Decrease time to build features and fix bugs

The quality of an application depends on testing a variety of scenarios to verify functionality. Carefully considering the business scenarios and automating those tests to run against cloud services will raise the quality of your application.

Software bugs and configuration problems have the least impact on cost and schedule when caught during an iterative development cycle. If issues remain undetected during development, finding and fixing in production requires more effort by more people.

A well planned serverless testing strategy will increase software quality and improve iteration time by verifying your Lambda functions and applications perform as expected in a cloud environment.

What to test

We recommend adopting a testing strategy that tests managed service *behaviors*, cloud configuration, security policies, and the integration with your code to improve software quality. *Behavior testing*, also known as black box testing, verifies a system works as expected without knowing all the internals.

- Run unit tests to check business logic inside Lambda functions.
- Verify integrated services are actually invoked, and input parameters are correct.
- Check that an event goes through all expected services end-to-end in a workflow.

In traditional server-based architecture, teams often define a scope for testing to only include code that runs on the application server. Other components, services, or dependencies are often considered external and out of scope for testing.

Serverless applications often consist of small units of work, such as Lambda functions that retrieve products from a database, or process items from a queue, or resize an image in storage. Each component runs in their own environment. Teams will likely be responsible for many of these small units within a single application.

Some application functionality can be delegated entirely to managed services such as Amazon S3, or created without using any internally developed code. There is no need to test these managed services, but you do need to test the integration with these services.

How to test serverless

You are probably familiar with how to test applications deployed locally: You write tests that run against code running entirely on your desktop operating system, or inside containers. For example, you might invoke a local web service component with a request and then make assertions about the response.

Serverless solutions are built from your function code and cloud-based managed services, such as queues, databases, event buses, and messaging systems. These components are all connected through an *event-driven architecture*, where messages, called *events*, flow from one resource to another. These interactions can be synchronous, such as when a web service returns results immediately, or an asynchronous action which completes at a later time, such as placing items in a queue or starting a workflow step. Your testing strategy must include both scenarios and test the interactions between services. For asynchronous interactions, you may need to detect side effects in downstream components that may not be immediately observable.

Replicating an entire cloud environment, including queues, database tables, event buses, security policies, and more, is not practical. You will inevitably encounter issues due to differences between your local environment and your deployed environments in the cloud. The variations between your environments will increase the time to reproduce and fix bugs.

In serverless applications, architecture components commonly exist entirely in the cloud, so testing against code and services in the cloud is necessary to develop features and fix bugs.

Testing techniques

In reality, your testing strategy will likely include a mix of techniques to increase quality of your solutions. You will use quick interactive tests to debug functions in the console, automated unit tests to check isolated business logic, verification of calls to external services with mocks, and occasional testing against emulators that mimic a service.

- [the section called “Testing in the cloud”](#): You deploy infrastructure and code to test with actual services, security policies, configurations and infrastructure specific parameters. Cloud-based tests provide the **most accurate** measure of quality of your code.

Debugging a function in the console is a quick way to test in the cloud. You can choose from a library of sample test events or create a custom event to test a function in isolation. You can also share test events through the console with your team.

To **automate** testing in the development and build lifecycle, you will need to test outside of the console. See the language specific testing sections in this guide for automation strategies and resources.

- [the section called “Testing with mocks”](#): Mocks are objects within your code that simulate and stand-in for an external service. Mocks provide pre-defined behavior to verify service calls and parameters. A *fake* is a mock implementation that takes shortcuts to simplify or improve performance. For example, a fake data access object might return data from an in-memory datastore. Mocks can mimic and simplify complex dependencies, but can also lead to more mocks in order to replace nested dependencies.
- [the section called “Testing locally using AWS SAM CLI”](#): Use AWS SAM CLI to locally invoke Lambda functions in Docker containers that use the same runtime environment as AWS Lambda. You can test function logic and event processing without deploying to the cloud.
- [the section called “Testing with emulation”](#): Use the [LocalStack integration in VS Code](#) to emulate multiple AWS services locally for testing service integrations.

Testing in the cloud

Testing in the cloud is valuable for all phases of testing, including unit tests, integration tests, and end-to-end tests. When you run tests against cloud-based code that also interacts with cloud-based services, you get the **most accurate** measure of quality of your code.

A convenient way to run a Lambda function in the cloud is with a test event in the AWS Management Console. A *test event* is a JSON input to your function. If your function does not

require input, the event can be an empty JSON document (`{}`). The console provides sample events for a variety of service integrations. After creating an event in the console, you can also share it with your team to make testing easier and consistent.

Learn how to [debug a sample function in the console](#).

Note

Although running functions in the console is a quick way to debug, **automating** your test cycles is essential to increase application quality and development speed.

Test automation samples are available in the [Serverless Test Samples repository](#). The following command line runs an automated [Python integration test example](#):

```
python -m pytest -s tests/integration -v
```

Although the test runs locally, it interacts with cloud-based resources. These resources have been deployed using the AWS Serverless Application Model and AWS SAM command line tool. The test code first retrieves the deployed stack outputs, which includes the API endpoint, function ARN, and security role. Next, the test sends a request to the API endpoint, which responds with a list of Amazon S3 buckets. This test runs entirely against cloud-based resources to verify those resources are deployed, secured, and work as expected.

```

For cloud-native application development, testing in the cloud provides the following benefits:

- You can test **every** available service.
- You are always using the most recent service APIs and return values.
- A cloud test environment closely resembles your production environment.
- Tests can cover security policies, service quotas, configurations and infrastructure specific parameters.
- Every developer can quickly create one or more testing environments in the cloud.
- Cloud tests increase confidence your code will run correctly in production.

Testing in the cloud does have some disadvantages. The most obvious negative of testing in the cloud is that deployments to cloud environments typically take longer than deployments to a local desktop environments.

Fortunately, tools such as [AWS Serverless Application Model \(AWS SAM\) Accelerate](#), [AWS Cloud Development Kit \(AWS CDK\) watch mode](#), and [SST](#) (3rd party) reduce the latency involved with cloud deployment iterations. These tools can monitor your infrastructure and code and automatically deploy incremental updates into your cloud environment.

Note

See how to [create infrastructure as code](#) in the *Serverless Developer Guide* to learn more about AWS Serverless Application Model, CloudFormation, and AWS Cloud Development Kit (AWS CDK).

Unlike local testing, testing in the cloud requires additional resources which may incur service costs. Creating isolated testing environments may increase the burden on your DevOps teams, especially in organizations with strict controls around accounts and infrastructure. Even so, when working with complex infrastructure scenarios, the cost in developer time to set up and maintain an intricate local environment could be similar (or more costly) than using disposable testing environments created with Infrastructure as Code automation tools.

Testing in the cloud, even with these considerations, is still the **best way** to guarantee the quality of your serverless solutions.

Testing with mocks

Testing with mocks is a technique where you create replacement objects in your code to simulate the behavior of a cloud service.

For example, you could write a test that uses a mock of the Amazon S3 service that returns a specific response whenever the **CreateObject** method is called. When a test runs, the mock returns that programmed response without calling Amazon S3, or any other service endpoints.

Mock objects are often generated by a mock framework to reduce development effort. Some mock frameworks are generic and others are designed specifically for AWS SDKs, such as [Moto](#), a Python library for mocking AWS services and resources.

Note that mock objects differ from emulators in that mocks are typically created or configured by a developer as part of the test code, whereas emulators are standalone applications that expose functionality in the same manner as the systems they emulate.

The advantages of using mocks include the following:

- Mocks can simulate third-party services that are beyond the control of your application, such as APIs and software as a service (SaaS) providers, without needing direct access to those services.
- Mocks are useful for testing failure conditions, especially when such conditions are hard to simulate, like a service outage.

- Mock can provide fast local testing once configured.
- Mocks can provide substitute behavior for virtually any kind of object, so mocking strategies can create coverage for a wider variety of services than emulators.
- When new features or behaviors become available, mock testing can react more quickly. By using a generic mock framework, you can simulate new features as soon as the updated AWS SDK become available.

Mock testing has these disadvantages:

- Mocks generally require a non-trivial amount of setup and configuration effort, specifically when trying to determine return values from different services in order to properly mock responses.
- Mocks are written, configured, and must be maintained by developers, increasing their responsibilities.
- You might need to have access to the cloud in order to understand the APIs and return values of services.
- Mocks can be difficult to maintain. When mocked cloud API signatures change, or return value schemas evolve, you need to update your mocks. Mocks also require updates if you extend your application logic to make calls to new APIs.
- Tests that use mocks might pass in desktop environments but fail in the cloud. Results may not match the current API. Service configuration and quotas cannot be tested.
- Mock frameworks are limited in testing or detecting AWS Identity and Access Management (IAM) policy or quota limitations. Although mocks are better at simulating when authorization fails or a quota is exceeded, testing cannot determine which outcome will actually occur in a production environment.

Testing locally using AWS SAM CLI

Use AWS SAM CLI to [test your functions in Docker containers](#) using the same runtime environment as AWS Lambda. You can test function logic and event processing locally without deploying to the cloud. If your function makes API calls to other AWS services, those calls will reach real AWS resources.

The advantages of testing with local containers include the following:

- Uses AWS Lambda runtime environments for accurate testing.
- Enables fast local development iterations without cloud deployment.
- Supports debugging with familiar local development tools.

Testing with local containers has these limitations:

- AWS service calls from your function will interact with real AWS resources, which may incur costs and affect production data.
- Requires Docker to be installed and running locally.

Testing with emulation

Emulators are locally running applications that mimic AWS services by providing similar APIs and return values. LocalStack is a popular emulation tool that provides a complete local development environment for testing service integrations.

LocalStack is an AWS Cloud emulator that you can use to test serverless applications locally. You can test Lambda functions that integrate with services like DynamoDB, Amazon S3, and Amazon SQS without connecting to actual AWS services. You can use [LocalStack in the AWS Toolkit for VS Code](#).

The advantages of test with emulators include the following:

- Emulators can facilitate fast local development iterations and testing.
- Emulators provide a familiar environment for developers used to developing code in a local environment. For example, if you're familiar with the development of an *n*-tier application, you might have a database engine and web server, similar to those running in production, running on your local machine to provide quick, local, isolated test capability.
- Emulators do not require any changes to cloud infrastructure (such as developer cloud accounts), so it's easy to implement with existing testing patterns.
- Because emulators don't use actual AWS resources, you won't get unexpected charges when starting multiple services or for letting some resources run for extended periods of time.

Testing with emulators has these disadvantages:

- Emulators can be difficult to set up and replicate, especially when used in CI/CD pipelines. This can increase the workload of IT staff or developers who manage their own software.
- Emulated features and APIs typically lag behind service updates. This can lead to errors because tested code does not match the actual API, and impede the adoption of new features.
- Emulators require support, updates, bug fixes, and feature parity enhancements. These are the responsibility of the emulator author, which could be a third-party company.

- Tests that rely on emulators may provide successful results locally, but fail in the cloud due to production security policies, inter-service configurations, or exceeding Lambda quotas.

Best practices

The following sections provide recommendations for successful serverless application testing.

You can find practical examples of tests and test automation in the [Serverless Test Samples repository](#).

Prioritize testing in the cloud

Testing in the cloud provides the most reliable, accurate, and complete test coverage. Performing tests in the context of the cloud will comprehensively test not only business logic but also security policies, service configurations, quotas, and the most up to date API signatures and return values.

Structure your code for testability

Simplify your tests and Lambda functions by separating Lambda-specific code from your core business logic.

Your Lambda function *handler* should be a slim adapter that takes in event data and passes only the details that matter to your business logic method(s). With this strategy, you can wrap comprehensive tests around your business logic without worrying about Lambda-specific details. Your AWS Lambda functions should not require setting up a complex environment or large amount of dependencies to create and initialize the component under test.

Generally speaking, you should write a handler that extracts and validates data from the incoming *event* and *context* objects, then sends that input to methods that perform your business logic.

Accelerate development feedback loops

There are tools and techniques to accelerate development feedback loops. For example, [AWS SAM Accelerate](#) and [AWS CDK watch mode](#) both decrease the time required to update cloud environments.

The samples in the GitHub [Serverless Test Samples repository](#) explore some of these techniques.

We also recommend that you create and test cloud resources as early as possible during development—not only after a check-in to source control. This practice enables quicker exploration

and experimentation when developing solutions. In addition, automating deployment from a development machine helps you discover cloud configuration problems more quickly and reduces wasted effort for updates and code review processes.

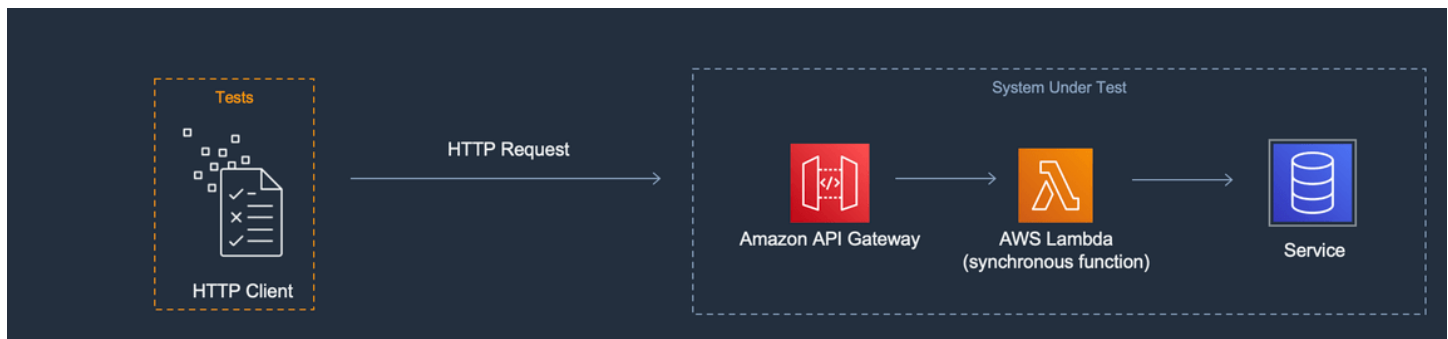

Focus on integration tests

When building applications with Lambda, testing components together is a best practice.

Tests that run against two or more architectural components are called *integration tests*. The goal of integration tests is to understand not only how your code will execute across components, but how the environment hosting your code will behave. *End-to-end tests* are special types of integration tests that verify behaviors across an entire application.

To build integration tests, deploy your application to a cloud environment. This can be done from a local environment or through a CI/CD pipeline. Then, write tests to exercise the system under test (SUT) and validate expected behavior.

For example, the system under test could be an application that uses API Gateway, Lambda and DynamoDB. A test could make a synthetic HTTP call to an API Gateway endpoint and validate that the response included the expected payload. This test validates that the AWS Lambda code is correct, and that each service is correctly configured to handle the request, including the IAM permissions between them. Further, you could design the test to write records of various sizes to verify your service quotas, such as max record size in DynamoDB, are set up correctly.

Create isolated test environments

Testing in the cloud typically requires isolated developer environments, so that tests, data, and events do not overlap.

One approach is to provide each developer a dedicated AWS account. This will avoid conflicts with resource naming that can occur when multiple developers working in a shared code base, attempt to deploy resources or invoke an API.

Automated test processes should create uniquely named resources for each stack. For example, you can set up scripts or TOML configuration files so that AWS SAM CLI [sam deploy](#) or [sam sync](#) commands will automatically specify a stack with a unique prefix.

In some cases, developers share an AWS account. This may be due to having resources in your stack that are expensive to operate, or to provision and configure. For example, a database may be shared to make it easier to set up and seed the data properly

If developers share an account, you should set boundaries to identify ownership and eliminate overlap. One way to do this is by prefixing stack names with developer user IDs. Another popular approach is to set up stacks based on **code branches**. With branch boundaries, environments are isolated, but developers can still share resources, such as a relational database. This approach is a best practice when developers work on more than one branch at a time.

Testing in the cloud is valuable for all phases of testing, including unit tests, integration tests, and end-to-end tests. Maintaining proper isolation is essential; but you still want your QA environment to resemble your production environment as closely as possible. For this reason, teams add change control processes for QA environments.

For pre-production and production environments, boundaries are typically drawn at the account level to insulate workloads from noisy neighbor problems and implement least privilege security controls to protect sensitive data. Workloads have quotas. You don't want your testing to consume quotas allocated for production (noisy neighbor) or have access to customer data. Load testing is another activity you should isolate from your production stack.

In all cases, environments should be configured with alerts and controls to avoid unnecessary spending. For example, you can limit the type, tier, or size of resources that can be created, and set up email alerts when estimated costs exceed a given threshold.

Use mocks for isolated business logic

Mock frameworks are a valuable tool for writing fast unit tests. They are especially beneficial when tests cover complex internal business logic, such as mathematical or financial calculations or simulations. Look for unit tests that have a large number of test cases or input variations, where those inputs do not change the pattern or the content of calls to other cloud services.

Code that is covered by unit tests with mocks should also be covered by testing in the cloud. This is recommended because a developer laptop or build machine environment could be configured differently than a production environment in the cloud. For example, your Lambda functions could use more memory or time than allocated when run with certain input parameters. Or your code

might include environment variables that are not configured in the same way (or at all), and the differences could cause the code to behave differently or fail.

The benefit of mocks is less for integration tests, because the level of effort to implement the necessary mocks increases with the number of connection points. End-to-end testing should not use mocks, because these tests generally deal with states and complex logic that cannot be easily simulated with mock frameworks.

Lastly, avoid using mocked cloud services to validate the proper implementation of service calls. Instead, make cloud service calls in the cloud to validate behavior, configuration, and functional implementation.

Use emulators sparingly

Emulators can be convenient for some use cases, for example, for a development team with limited, unreliable, or slow internet access. But, in most circumstances, choose to use emulators sparingly.

By avoiding emulators, you will be able to build and innovate with the latest service features and up to date APIs. You will not be stuck waiting on vendor releases to achieve feature parity. You will reduce your upfront and ongoing expenses for purchasing and configuration on multiple development systems and build machines. Moreover, you will avoid the problem that many cloud services simply do not have emulators available. A testing strategy that depends on emulation will make it impossible to use those services (leading to potentially more expensive workarounds) or produce code and configurations that aren't well tested.

When you do use emulation for testing, you must still test in the cloud to verify configuration and to test interactions with cloud services that can only be simulated or mocked in an emulated environment.

Challenges testing locally

When you use emulators and mocked calls to test on your local desktop you might experience testing inconsistencies as your code progresses from environment to environment in your CI/CD pipeline. Unit tests to validate your application's business logic on your desktop may not accurately test critical aspects of the cloud services.

The following examples provide cases to watch out for when testing locally with mocks and emulators:

Example: Lambda function creates an S3 bucket

If a Lambda function's logic depends on creating an S3 bucket, a complete test should confirm that Amazon S3 was called and the bucket was successfully created.

- In a mock testing setup, you might mock a success response and potentially add a test case to handle a failure response.
- In an emulation testing scenario, the **CreateBucket** API might be called, but you need to be aware that the identity making the local call will **not** originate from the Lambda service. The calling identity will not assume a security role as it would in the cloud, so a placeholder authentication will be used instead, possibly with a more permissive role or user identity that will be different when run in the cloud.

The mock and emulation setups will test what the Lambda function will do if it calls Amazon S3; however, those tests will not verify that the Lambda function, as configured, is capable of successfully creating the Amazon S3 bucket. You must make sure the role assigned to the function has an attached security policy that allows the function to perform the `s3:CreateBucket` action. If not, the function will likely fail when deployed to a cloud environment.

Example: Lambda function processes messages from an Amazon SQS queue

If an Amazon SQS queue is the source of a Lambda function, a complete test should verify that the Lambda function is successfully invoked when a message is put in a queue.

Emulation testing and mock testing are generally set up to run the Lambda function code directly, and to simulate the Amazon SQS integration by passing a JSON event payload (or a deserialized object) as the function handler's input.

Local testing that simulates the Amazon SQS integration will test what the Lambda function will do when it's called by Amazon SQS with a given payload, but the test will not verify that Amazon SQS will successfully invoke the Lambda function when it is deployed to a cloud environment.

Some examples of configuration problems you might encounter with Amazon SQS and Lambda include the following:

- Amazon SQS visibility timeout is too low, resulting in multiple invocations when only one was intended.

- The Lambda function's execution role doesn't allow reading messages from the queue (through `sqs:ReceiveMessage`, `sqs:DeleteMessage`, or `sqs:GetQueueAttributes`).
- The sample event that is passed to the Lambda function exceeds the Amazon SQS message size quota. Therefore, the test is invalid because Amazon SQS would never be able to send a message of that size.

As these examples show, tests that cover business logic but not the configurations between cloud services are likely to provide unreliable results.

FAQ

I have a Lambda function that performs calculations and returns a result without calling any other services. Do I really need to test it in the cloud?

Yes. Lambda functions have configuration parameters that could change the outcome of the test. All Lambda function code has a dependency on [timeout](#) and [memory](#) settings, which could cause the function to fail if those settings are not set properly. Lambda policies also enable standard output logging to [Amazon CloudWatch](#). Even if your code does not call CloudWatch directly, permission is needed to enable logging. This required permission cannot be accurately mocked or emulated.

How can testing in the cloud help with unit testing? If it's in the cloud and connects to other resources, isn't that an integration test?

We define *unit tests* as tests that operate on architectural components in isolation, but this does not prevent tests from including components that may call other services or use some network communication.

Many serverless applications have architectural components that can be tested in isolation, even in the cloud. One example is a Lambda function that takes input, processes the data, and sends a message to an Amazon SQS queue. A unit test of this function would likely test whether input values result in certain values being present in the queued message.

Consider a test that is written by using the Arrange, Act, Assert pattern:

- *Arrange*: Allocate resources (a queue to receive messages, and the function under test).
- *Act*: Call the function under test.
- *Assert*: Retrieve the message sent by the function, and validate the output.

A mock testing approach would involve mocking the queue with an in-process mock object, and creating an in-process instance of the class or module that contains the Lambda function code. During the Assert phase, the queued message would be retrieved from the mocked object.

In a cloud-based approach, the test would create an Amazon SQS queue for the purposes of the test, and would deploy the Lambda function with environment variables that are configured to use the isolated Amazon SQS queue as the output destination. After running the Lambda function, the test would retrieve the message from the Amazon SQS queue.

The cloud-based test would run the same code, assert the same behavior, and validate the application's functional correctness. However, it would have the added advantage of being able to validate the settings of the Lambda function: the IAM role, IAM policies, and the function's timeout and memory settings.

Next steps and resources

Use the following resources to learn more and explore practical examples of testing.

Sample implementations

The [Serverless Test Samples repository](#) on GitHub contains concrete examples of tests that follow the patterns and best practices described in this guide. The repository contains sample code and guided walkthroughs of the mock, emulation, and cloud testing processes described in previous sections. Use this repository to get up to speed on the latest serverless testing guidance from AWS.

Improving startup performance with Lambda SnapStart

Lambda SnapStart can provide as low as sub-second startup performance, typically with no changes to your function code. SnapStart makes it easier to build highly responsive and scalable applications without provisioning resources or implementing complex performance optimizations.

The largest contributor to startup latency (often referred to as cold start time) is the time that Lambda spends initializing the function, which includes loading the function's code, starting the runtime, and initializing the function code. With SnapStart, Lambda initializes your function when you publish a function version. Lambda takes a [Firecracker microVM](#) snapshot of the memory and disk state of the initialized [execution environment](#), encrypts the snapshot, and intelligently caches it to optimize retrieval latency.

To ensure resiliency, Lambda maintains several copies of each snapshot. Lambda automatically patches snapshots and their copies with the latest runtime and security updates. When you invoke the function version for the first time, and as the invocations scale up, Lambda resumes new execution environments from the cached snapshot instead of initializing them from scratch, improving startup latency.

Important

If your applications depend on uniqueness of state, you must evaluate your function code and verify that it is resilient to snapshot operations. For more information, see [Handling uniqueness with Lambda SnapStart](#).

Topics

When to use SnapStart

Lambda SnapStart is designed to address the latency variability introduced by one-time initialization code, such as loading module dependencies or frameworks. These operations can sometimes take several seconds to complete during the initial invocation. Use SnapStart to reduce this latency from several seconds to as low as sub-second, in optimal scenarios. SnapStart works best when used with function invocations at scale. Functions that are invoked infrequently might not experience the same performance improvements.

SnapStart is particularly beneficial for two main types of applications:

- **Latency-sensitive APIs and user flows:** Functions that are part of critical API endpoints or user-facing flows can benefit from SnapStart's reduced latency and improved response times.
- **Latency-sensitive data processing workflows:** Time-bound data processing workflows that use Lambda functions can achieve better throughput by reducing outlier function initialization latency.

[Provisioned concurrency](#) keeps functions initialized and ready to respond in double-digit milliseconds. Use provisioned concurrency if your application has strict cold start latency requirements that can't be adequately addressed by SnapStart.

Supported features and limitations

SnapStart is available for the following [Lambda managed runtimes](#):

- Java 11 and later
- Python 3.12 and later
- .NET 8 and later. If you're using the [Lambda Annotations framework for .NET](#), upgrade to [Amazon.Lambda.Annotations](#) version 1.6.0 or later to ensure compatibility with SnapStart.

Other managed runtimes (such as `nodejs24.x` and `ruby3.4`), [OS-only runtimes](#), and [container images](#) are not supported.

SnapStart does not support [provisioned concurrency](#), [Amazon Elastic File System \(Amazon EFS\)](#), or ephemeral storage greater than 512 MB.

Note

You can use SnapStart only on [published function versions](#) and [aliases](#) that point to versions. You can't use SnapStart on a function's unpublished version (\$LATEST).

Supported Regions

Lambda SnapStart is available in all [commercial Regions](#) except Asia Pacific (New Zealand) and Asia Pacific (Taipei).

Compatibility considerations

With SnapStart, Lambda uses a single snapshot as the initial state for multiple execution environments. If your function uses any of the following during the [initialization phase](#), then you might need to make some changes before using SnapStart:

Uniqueness

If your initialization code generates unique content that is included in the snapshot, then the content might not be unique when it is reused across execution environments. To maintain uniqueness when using SnapStart, you must generate unique content after initialization. This includes unique IDs, unique secrets, and entropy that's used to generate pseudorandomness. To learn how to restore uniqueness, see [Handling uniqueness with Lambda SnapStart](#).

Network connections

The state of connections that your function establishes during the initialization phase isn't guaranteed when Lambda resumes your function from a snapshot. Validate the state of your network connections and re-establish them as necessary. In most cases, network connections that an AWS SDK establishes automatically resume. For other connections, review the [best practices](#).

Temporary data

Some functions download or initialize ephemeral data, such as temporary credentials or cached timestamps, during the initialization phase. Refresh ephemeral data in the function handler before using it, even when not using SnapStart.

SnapStart pricing

Note

For Java managed runtimes, there's no additional cost for SnapStart. You're charged based on the number of requests for your functions, the time that it takes your code to run, and the memory configured for your function.

The cost of using SnapStart includes the following:

- **Caching:** For every function version that you publish with SnapStart enabled, you pay for the cost of caching and maintaining the snapshot. The price depends on the amount of [memory](#) that you allocate to your function. You're charged for a minimum of 3 hours. You will continue to be charged as long as your function remains [active](#). Use the [ListVersionsByFunction](#) API action to identify function versions, and then use [DeleteFunction](#) to delete unused versions. To automatically delete unused function versions, see the [Lambda Version Cleanup](#) pattern on Serverless Land.
- **Restoration:** Each time a function instance is restored from a snapshot, you pay a restoration charge. The price depends on the amount of memory you allocate to your function.

As with all Lambda functions, duration charges apply to code that runs in the function handler. For SnapStart functions, duration charges also apply to initialization code that's declared outside of the handler, the time it takes for the runtime to load, and any code that runs in a [runtime hook](#). Duration is calculated from the time that your code begins running until it returns or otherwise ends, rounded up to the nearest 1 ms. Lambda maintains cached copies of your snapshot for resiliency and automatically applies software updates, such as runtime upgrades and security patches to them. Charges apply each time that Lambda re-runs your initialization code to apply software updates.

For more information about the cost of using SnapStart, see [AWS Lambda Pricing](#).

Activating and managing Lambda SnapStart

To use SnapStart, activate SnapStart on a new or existing Lambda function. Then, publish and invoke a function version.

Activating SnapStart (console)

To activate SnapStart for a function

1. Open the [Functions page](#) of the Lambda console.
2. Choose the name of a function.
3. Choose **Configuration**, and then choose **General configuration**.
4. On the **General configuration** pane, choose **Edit**.
